So far as infrahuman organisms are concerned, there is the greatest divergence from type to type in respect to the time of the opening of the eyes. The subject was early investigated, Emmert, one of the first students of fetal mammals, having studied this phenomenon in the mouse (Emmert and Bugatzy, 1818). Certainly no generalizations can be made from form to form in regard to eyelid activities at the time of birth. The guinea pig is born with eyes open and apparently in an adult functional condition, whereas the lids of the rat do not gain their adult condition until the sixteenth or seventeenth postnatal day (Lane, 1917). Warkentin and Smith (1937) and Warkentin (1938) have studied the development of a number of visual functions by various techniques in developing animals. (See also Mowrer, 1936, for a general consideration of learning versus maturation in this field.)

In summary. Concerning vision in the fetus it can be said that the specific morphological changes that lie behind the development of the visual mechanism occur from possibly the second week after fertilization until well after birth. Light stimuli at intense levels ordinarily do not affect the retina before birth, but in premature infants it can be shown that the eye is probably sufficiently structurally developed before birth to make possible the light or iris reflex and the differentiation between light and dark. The functional development of the neuromuscular apparatus of the eye is also gradual. Indications have been obtained in regard to the relationship between vestibular stimulation and eye movements before birth which suggest that vestibular control is more primitive than visual control. Eyelid reactions are also found to undergo a progressive series of changes before normal birth.

THE SENSES IN GENERAL RELATIONSHIP TO THE ONSET OF MENTAL LIFE IN THE PRENATAL PERIOD

For the psychologist there are at least two major problems connected with the study of the senses. The first of these is the classic problem of the relationship between the

senses and what the philosophers have long called conscious experience. The second is the relationship between receptor activity and the initiation, modification, and control of behavior. As noted above, this control must be considered in certain cases to include a continuous "feedback" relationship with existing continuous or periodic activity (Wiener, 1948). Many psychologists, on the basis of some excellent reasons, hold that ultimately these two problems reduce to one, as Langfeld (1931) and others have urged in the interpretation of consciousness in terms of response. Historically, however, and indeed at the present time, the two problems are ordinarily treated as separate, or at any rate as separable. Some prefer to say that consciousness and behavior are aspects of the total functional description of the relationship between the adult (or immature) human organism and its environment. Here, although no attempt will be made to find an ultimate answer to the question whether these problems are really one or two, they will be treated as independent.

A study of the fetal senses contributes little to our knowledge of the so-called introspective psychology of consciousness. There has been some speculation concerning sensory experience before birth, but little of scientific validity has been written. As incidentally noted above, several of the empiricist philosophers concerned themselves with prenatal life. John Locke (1849 edition) did not neglect the possibility that some dim ideas were present before birth. Cabanis (Genzmei, 1882) held that quite elaborate sensory experiences were present in the fetus, even to the consciousness of self (Cf. Compayré, 1896). Kussmaul (1859) held that the child came into the world with a dim perception of an outer world. Peyer (1882) also attributed experience of a sort to the fetus. Peterson and Rainey (1910) say "The newborn comes into the world with a small store of experience and associated feelings and a shadowy consciousness."

Such observations could be added to by other excerpts from early psychologists, but on the whole they seem profitless. Compayré (1896), more than 70 years ago, summarized the scientific arguments against such speculations as well as against the fancies of the Neo-Platonists that "our birth is but a sleep

and a forgetting." The gist of his argument is that there can be no evidence on the matter. With this point of view the writer is in accord.

James (1890) and, more recently, Koffka (1924) and his associates made much of the fact that in early postnatal life specific experiences, like specific acts of behavior, become individuated out of totalities rather than at first synthesized out of discrete elements. Thus James (1890, Vol. I) says "The baby, assailed by eyes, ears, nose, skin, and entrails at once, feels it all as one great blooming, buzzing confusion." And again "Our original sensible totals are, on the one hand, subdivided by discriminative attention, and, on the other, united with other totals." Koffka (1924) similarly asserts "From an unlimited and ill-defined background there has arisen a limited and somewhat definite phenomenon, a quality." Certainly if these descriptions are adequate to the experiential life of the neonate, there is no reason to suppose that they may not also be adequate, although possibly in a still vaguer form, to conscious fetal life. If the writer were asked to make a guess in regard to the matter, he would say that he feels that the description given above by Koffka is probably relatively adequate as a description of the development of fetal conscious experience. It may be pointed out that such experience may parallel reactions to many different and quite specific types of receptor stimuli.

So far as the present writer is concerned, there is no objection to applying to ontogeny, that is, growth in the individual, a point of view similar to that now generally accepted in regard to the growth of consciousness in the development of the animal series. Such judgments must be treated as complex inferences, however, and not as facts of observation. The writer further points out that a scientific definition of the word "consciousness" as commonly used has not yet been presented in a form to win general acceptance. The problem of the nature of consciousness and its relation to the brain is still viewed as a scientific and not merely as a philosophical question. A recent book, *Brain and Conscious Experience*, edited by J. C. Eccles (1966), is devoted largely to a consideration of the concept of consciousness from the point of view of neurophysiology.

The second large problem which concerns the psychologist in relation to receptor activity has grown out of the approach to the study of mental life which deals explicitly with the processes of behavior. The problem of the receptor or, possibly better, of stimulus control of behavior is, however, much older than the so-called school of behaviorism. Kussmaul (1859) explicitly defended this view in undertaking his study of premature and normal newborn infants. It is related to a much more general position, as is the view expressed by Forel and quoted by Canestrini (1913) "Das wahre Baumaterial der Organismen liefern die Reize der Aussenwelt." One who takes a type of "communication theory" approach to behavior can consider that all behavior is a result of genetically determined responses that result from mutations that led to survival in the ancestors of each organism or to encoded environmentally determined learning in the individual under consideration.

It seems more and more certain that, whatever else scientific psychology may do, it must thus concern itself increasingly with the relationship between the environment external to the receptors, be they exteroceptors, interoceptors, or proprioceptors, and to the responses of the organism to such stimulation. In any consideration of fetal psychology, therefore, special attention should be given to the facts of the stimulus control of behavior. In order to understand this relationship, it will be necessary to review the current status of fact and theory in regard to the causes underlying the beginning and differentiation of activity in the fetal organism. This consideration may well serve as a conclusion to this chapter, because any such discussion will necessarily involve a review of many of those processes of fetal life which are even inferentially significant for general psychology. For an excellent consideration of this general field see Hooke (1942, 1952, etc.).

In the beginning of this chapter, something was said of the early processes of morphogenesis in the developing organism. It was suggested that the point should be kept continually in view by one who is interested in behavioral development, that the general growth of structure and function always occurs in an organism that is in an environment. Organisms do not live or grow in a physical

or biological vacuum. From the first cell division in the developing individual, each process of structural and functional modification is, moreover, to be considered as a complex resultant of activities. Some of these determinants are intrinsic in the cell and are, indeed, in the correct sense of the term hereditary, but such intrinsic determinants always act in a dynamic system which is also subjected to extrinsic influences. Development is apparently always a resultant of these two sets of forces working *interdependently*. For some of the evidence on this matter, see earlier papers by Carmichael (1925, 1938). Sharp (1926) summarizes this point of view when he says in his consideration of general cytology:

The cell should not be thought of as a static structure. It is rather a dynamic system in a constantly changing state of molecular flux, its constitution at any given moment being dependent upon antecedent states and upon environmental conditions.

To put this in another way, the problem is not whether a given type of behavior is a result of heredity or environment. This is true because the environment is essential in the development of all inherited mechanisms that determine behavior. The real question is to determine whether a behavior act under study is a result of the work of the genetic code or of the individually determined engram.

If space permitted a review of the present status of that part of scientific embryology which is devoted to developmental mechanics, it would become apparent that the process of growth in the organism involves a most complex series of energy relationships, some of which, it seems probable, have as yet only begun to be unraveled. (See Arshavsky, 1967)

Joseph Altman (1966), in his consideration of the organic foundations of animal behavior, well considers the relationship just discussed in terms of different modes of neural and behavioral programming. He emphasizes three phases:

- 1 Fixed morphogenetic programming, which occurs without individual experience and is not generally altered by experience.
- 2 Modifiable epigenetic programming,

which consists of essential inborn components but requires individual experience for its realization. Acquired transactional programming, in which new schemata of behavior are formed on the basis of individual experience

There seems, therefore, to be excellent evidence for the view elsewhere discussed by the writer (1925) at greater length that, from the movement that growth has begun in the fertilized ovum until senescence or death, development consists of the alteration of existing structures and functions in an organism living in a continually changing environment. It cannot be overemphasized that there is both an external and an internal environment. As noted elsewhere in this chapter, the alterations that take place in the chemistry of the blood stream, which supplies the central nervous system, are fundamental in altering the way in which this system responds to the afferent neural impulses which come in from its receptors.

Above all, it must be remembered that the genetic code continues to influence growth and behavior as long as the organism lives.

Conel (1939-1963) has studied in detail the postnatal development of the human cerebral cortex. This elaborate series of investigations discusses the cytoarchitectonic pattern of the cerebral cortex at various early postnatal ages. This investigator points out, for example, that the behavior of the human infant during the first month of life may be mediated by subcortical centers. He concludes, "The gradual development of the structural components of the cortical mechanism suggests that function also develops gradually." Noback (1959) has also worked in this area.

In the area of human neonatal sleep, Bahtoshuk (1964) has investigated four areas of awake and sleep samples using the electroencephalographic techniques.

Hamburger and his associates (1957, 1963, 1964, 1965, 1966, 1967) in a general consideration of the ontogeny of behavior and its structural basis presents strong evidence for his previously expressed view that the early development of behavior is genetically determined. He says, "The architecture of the nervous system and the concomitant behavior patterns result from self-generating growth and maturation processes that are determined entirely by inherited intrinsic factors, to the

exclusion of functional adjustment, exercise or anything else akin to learning."

The fact that learning is possible in fetal life has been noted previously in this chapter. This question can thus be raised: To what degree are the normal behavior changes that are observed in the early ontogenetic development of any typical mammal or in man a result of specific individual environmental stimulation (i.e., to some type of learning or conditioning) or the result of the working out of the genetic code?

Ray (1932) has attempted to condition fetal responses. Spelt (1938), using the auditory responses of the fetus described above, has reported the conditioning of the human fetus. These and other studies of early postnatal learning may be taken as demonstrating that the neural mechanism of the late fetus has matured to a level at which environmentally determined learning is possible. This, of course, should not be taken as indicating that *all* behavior changes after learning has begun is a result of further learning.

The present author will try, in the following paragraphs, to suggest one answer to this old and crucially important question on the basis of his years of observation of fetal behavior and his study of the publications of others in this field. No claim is made for originality in what is presented here, and it will not always be possible to cite specific references for the ideas that are given. This is a field in which much active research and theoretical writing is in progress and anything asserted about it at one time must always be considered subject to change as additional scientific evidence is secured.

As has been pointed out before, it is a truism that all behavior depends on structure. Behavior, indeed, is structure in action. Behavior is anything a human being or other animal does. Structure in the sense used here may be at the molecular as well as at the molar level. As has been said more than once in this chapter, the developing organism always exists in an environment. The genetic code of each species has indeed evolved in organisms that exist in what may be called "normal" prenatal and postnatal environments for the species. Fuller and Thompson (1960) well express this fact: "The development of any trait always involves genetic and environmental determinants" and "a trait is called

hereditary if most of the variation within a population is associated with genetic endowment"

Today there seems little doubt that it can be asserted with assurance that in all mammals including man, early behavior is a result of the activation of structures that are as they are largely as a result of genetic endowment. Typical of such behavior is the elaborate repertory of specific responses that the present author has described above, to take but one example, as characterizing the developing prenatal guinea pig. This is true "species-specific behavior." It is possible to quibble about the words used, but there can be no doubt that these standard prenatal reactions are as surely hereditary as in hair color, tooth pattern, or species-specific skeletal makeup.

As any mammal passes through ontogenetic development, it comes to a stage or period at which some type of learning or conditioning can be demonstrated as important in determining the adjustments that the individual mammal makes to the environment in which it is adaptively existing. This does not mean that the genetic code has ceased to operate in the altering of some of the structures on which some observable behavior change depends. In other words, even after an animal can learn, some of its behavior changes are a result of maturation rather than learning. There is, therefore, in postnatal life, a close and interlocking interrelationship between "maturation" and "learning" in determining the multitudinous specific structural changes on which new adaptive acts depend. In this connection, a point should be emphasized again that is clearly made by Margaret Green (1966). She says, "In multicellular organisms many kinds of cells are formed and it is clear that although each kind contains the whole array of genes present in the zygote, only certain genes are active in each different kind of cell. In some way, genes are called into action at particular times and promote changes which may then call certain other genes into action or repress activity of others already active."

It may be helpful here to consider this mechanism of embryologic growth and of behavior change in different words. No one doubts that if any population of organisms is to survive and reproduce its kind and escape extinction, enough of its members must

adapt successfully to what is ordinarily its own geographically isolated niche so as to allow the essential reproductive activity that alone makes it possible for the gene pool of the population of organisms in question to remain at a viable level. This means that each species of organism and its environment must communicate at all times and they must communicate in an adaptive way. The genetic code may thus be thought of as a record or, to use a standard analogy, as a "punch card" by means of which adaptive communication between the ancestors of the living members of a species and their environments have taken place and allowed the origin and the viable life of the ancestors of present representatives of any species. Each phylogenetic code has developed by mutation and the organisms possessing such codes are those that survive as a result of all the processes called "natural selection."

Because of its inborn genetic code, therefore, each new organism is able to communicate adaptively with its environment on a basis that is similar in some respects to that which previously allowed the survival of its ancestors.

As Hirsch (1962) well says, "We cannot understand the behavior of an organism without understanding the organism not only as an integrated and coordinated system responsive to its environment but also as a member of a population with a unique evolutionary history adapting it to the niche it presently occupies."

In the ontogeny of the human beings and all other mammals, as just pointed out, the genetic code produces a stage or stages at which adaptive changes are not only made on the basis of ancestral information concerning what is adaptive, in communication between the organism and its environment, but also in the production of a new, vitally important characteristic by means of which new environmental information can produce structural changes basic to individual habits or other individually determined acts of adaptive behavior. That is, the genetic code determines a level or a series of levels of development at which learning or specific types of learning are possible. Barlow (1961), in considering the physiology of sensory inputs, emphasizes that such messages are compressed by removing redundancy and

thus suggests the idea that the code which compresses messages may also constitute the basis of memory (See paragraphs on perception above)

This view that the changes of behavior that result from both maturation and learning are to be considered as dependent on mechanisms by means of which an organism "communicates" with its environment needs much further study and amplification. It may be that the key to both these processes will be found in a new understanding of the engram. In this sense the term engram is used to describe the physical basis of habit, that is, a hypothetical more or less permanently altered state of living tissue resulting from previous excitation. If this view is adopted, it may be said that just as a record of the successful communications between a species of organisms and their environments (which have led to survival) are stored in the DNA-RNA mechanisms, so also it may be that individual adaptive changes in behavior which are based on learning are dependent on individually acquired coded molecular changes.

It is clear that the changes established by individual experience do not directly alter the phylogenetic code. This code is carried in the germ cells of each succeeding generation until changed by mutation. Biology has clearly demonstrated that the so-called Lamarckian theory of evolution—that acquired characteristics somehow become hereditary characters—is not true. In other words, except as mutations change the code of the germ cells of populations of organisms the adaptive acts of the adults of any population do not alter the basic genetic code of that population.

The two codes mentioned above do, however, play complex roles in the determination of the structures, whether molecular or molar—on which the adaptive responses of organisms to the information secured from the environment at any time depend. The full ontogeny of individual behavior can thus be thought of as dependent in an intricate way on both of these coded systems. An example may make this more clear. The terrestrial locomotion of mammals, including men, can, as indicated above, be shown to depend in a basic way on the genetic code and also upon the particular engram system

of the individual, which has been determined by the organism's specific learned habits of locomotion in the particular environment in which it exists and has developed. The complexity of this problem is well analyzed by Hyden (1967, 1967a) in his paper on behavior, neural function, and RNA.

As already suggested, there is much that is still speculative in the consideration of the role of phylogenetic and ontogenetic codes, as just presented, but this view is given here as a means of stimulating further study and research. For a consideration of some of the problems involved in thinking of a chemical basis of learning of the sort suggested here the reader should consult a paper and references given by Agranoff (1967) in a consideration of memory and protein synthesis. In a consideration of the chemical basis of memory, see Fleener, Fleener, and Stellar (1963, 1967) and the references given by them.

The immediately preceding paragraphs contain statements that must be viewed today as speculative. What has been written is intended to suggest that scientific work of great importance is now in progress that may soon give a firm scientific basis for an understanding of the growth of normal and abnormal behavior and of applied procedures to modify behavior, whether the molecular basis of such behavior is seen to be "inborn" or "acquired." This will then indeed show how important it is for the psychologist to understand the onset and early development of behavior.

The student who wishes further study in this field should consult, besides the detailed references given, papers by Hooker (1936, 1939a, 1942, 1943, and especially 1952), which summarize much of the work in this field, the summary of the early work on the development of behavior by Dewey (1935), and the important book *Physiology of the Fetus: Origin and Extent of Function in Prenatal Life* by Windle (1940). Chapter 17, "The embryology of behavior" in Maier and Hamilton (1966) is an especially valuable short introduction to this field.

The late Sir Joseph Barcroft's important work, to which many references are given in this chapter, is also summarized in a book, *Researches on Pre-Natal Life* (1946). Early development in general is summarized in a

chapter, "Ontogenetic Development," by Carmichael in the *Handbook of Experimental Psychology*, edited by S S Stevens, 1951

This chapter may well end by two quotations from poets. The first is from Oliver Wendell Holmes (noted by living in his foreward to Smith's excellent *The Physiology of the Newborn Infant*, 1946)

So the stout fetus, kicking and alive,
Leaps from the fundus for his final dive
Tired of the prison where his legs were
 curled
He pants, like Rasselas, for a wider world

No more to him their wanted joys afford
The finged placenta and the knotted cord

The second is prose, written by a poet—
Coleridge (1885)

Yes—the history of a man for the nine months preceding his birth would probably be far more interesting and contain events of greater moment, than all the three score and ten years that follow it!

Poets have a way of understanding what psychologists sometimes miss!

7. *Studies of Early Experience*¹

WILLIAM R. THOMPSON AND JOAN E. GRUSEC

Developmental psychology, with which this book is concerned, has tended to employ two major methodological orientations to its subject-matter. The first—and certainly the more usual—is the *normative-descriptive*. This has been the approach traditionally taken by most workers in child psychology. The kinds of datum gathered by Gesell and his colleagues at Yale are prototypic of this approach in that they are basically descriptions of the behavior of children at each chronological age level. The work of Piaget and others at Geneva has been similar, although the use of simple age as the major anchoring variable has been rather less emphasized. That is to say, Piaget has attempted to derive stages based on *developmental* sequences, although these are not necessarily perfectly correlated with chronological age. Ultimately, however, such so-called stages are based on description supplemented by a good deal of guesswork and without much reference to any basic theoretical conceptualizations of whether there are changes taking place in the developing organism that demand such psychological transitions.

The second orientation is the *experimental-predictive*. Here the focus is less on empirical assays of what the organism is like at certain periods of its development than on the later outcomes of certain treatments that are imposed either by nature or by deliberate experimental manipulation early in life. The

retrospective clinical investigations of Freud—though he himself did virtually no work with children—belong to this orientation, as does most of the work done on development in animals, that is, the so-called studies of early experience.

It is of some importance to note that the two approaches have seldom been combined, for a variety of historical reasons. Thus we find very little attention paid, in most of the work on early experience, to descriptions of the behavioral characteristics of a young animal, which might permit the isolation of those characteristics responsible for determining the later residua of whatever treatment the experimenter has imposed. On the other hand, most child psychologists have been content to deal with their subjects descriptively at some particular age level as if they all occupied a kind of neutral and uniform environment and had no past and no future.

One result of this disparity between the two orientations has been an almost complete lack of fruitful theorizing pertaining uniquely to the area of developmental psychology. There are certainly broad schemas such as those of Gesell (1946) and Werner (1957), but these have not readily been translatable into sets of specific questions that can be asked and answered in a precise experimental manner. The same can be said of at least many of the conceptions of Piaget. On the animal side, we again find a lack of theorizing and, instead, an endless proliferation of studies dealing with more and more exotic independent and dependent variables. These experiments leave no doubt that early experience is extremely important. But they do not explore the nature of the residual effects nor

¹ This chapter was prepared with the aid of grants from the National Research Council, the Arts Research Committee of Queen's University, and the Ontario Alcohol and Drug Addiction Research Foundation.

the manner in which they are stored by organisms at a young age. Yet these are the basic issues we wish to understand.

THE ESSENTIAL PROBLEM

It is easy to demonstrate that a rat or mouse that has been handled, shocked, vibrated, cooled, or heated as an infant behaves differently from an animal that has not undergone such treatments. As we just stated, early experience is important. This is a simple enough postulate, yet its terms are rich in possible meanings. "Early experience" covers presumably all age levels from conception to maturity—a lengthy period during which the experiences of animals with respect to some imposed treatment cannot be uniform. The response of a human fetus to anxiety in its mother surely cannot be the same as that of the four-year-old child and hence the residual effects of these experiences, if any, are bound to be different. The question we must ask is how the early period of life can be broken up in a manner that takes account, not so much of the changes in chronological age that are occurring, but rather of the changes in developmental characteristics that are also going on. For although these latter changes must vary with age, the relationships they may have with age are not necessarily one to one. Age proceeds, by definition, in terms of uniform increments. Such developmental variables as differentiation and growth, however, are usually considered to be sigmoid or logistic in form. When we attempt to make predictions about the effects some early experience may have later in life, it is such basic dimensions as these to which we should turn our attention.

What we are suggesting, in short, is that more information be obtained about the properties—physiological and psychological—of young organisms and that these be used to formulate theoretical models that will put more predictive potency into the rationale that lies behind the study of early experience.

The same kind of examination must be made of the term "important." It is very seldom that any careful definition of this key word is attempted. Schaefer and one of the writers (Thompson and Schaefer, 1961) suggested it must involve the following dimensions:

- 1 Extent of change in a particular function, for example, the size of increment or decrement in open-field activity as shown by a treated group of animals as compared with controls.

- 2 The potential reversibility of the change that is, how easy or difficult it is, by using special procedures, to produce a reversion to the control level.

- 3 The permanence or duration of the change, that is, the lack of any tendency for treated animals spontaneously to drift back to a normal level.

- 4 The generality of the change—meaning simply the number of discrete functions or structures affected by the treatment.

Together, these constitute the operational meaning of "important" when we use this term in connection with the effects of early experience.

One further point must be made most emphatically. The meanings specified above can have usefulness only when the experimental comparisons made are of a four-way type that is, between young treated and nontreated and adult treated and nontreated groups. The use of such a 2×2 design is usually impracticable with human subjects for obvious reasons, but with animals it should be (though it seldom is) regarded as mandatory. Obviously, we can say little about the unique characteristics of young systems unless we can compare them with adult organisms.

Besides a formal explication of the phrase "early experience is important," we may arrive at some understanding of the theoretical problems that are latent in the phrase by sketching the historical background out of which empirical work arose. Let us now examine this.

HISTORY OF WORK ON EARLY EXPERIENCE

The history of the general problem as it has been commonly understood is far broader in scope than the history of the problem as we have more precisely defined it. That is to say, there has been a great deal of work done on topics like the nature of growth, the problem of maturation versus learning, the modifiability of child intelligence by special procedures such as orphanage rearing, nursery

school experience, and the like. However, in only a few of these areas has there been any real theoretical interest in or experimental provision for deducing from the data critical information about properties that may distinguish the young from the mature organism. To take an example, during the late 1930s and early 1940s, a series of studies was carried out by Wellman, Skeels, Skodak and others at Iowa purporting to show that the IQs of mentally defective children could be significantly raised by exposure to special schooling. Institution rearing, on the other hand, was supposed to have the opposite effect. These results were subsequently challenged by a number of critics, including especially Goodenough (1939) and McNemar (1940), on the grounds of inadequate control and statistical procedure. Consequently, their validity must be considered doubtful, but whatever the case, certainly no conclusion can be drawn from such data regarding the importance of the *youth* of the subjects as a major factor influencing the outcome. The interest of the Iowa group was more broadly in the problem of modifiability of intelligence in general rather than merely in young systems. Thus such studies stand a little apart from the category we wish mainly to consider in this chapter.

The commitment that must define this category—and it may be held implicitly and explicitly—is to the notion that an experience imposed on an organism will have different effects according to whether it is mature or immature since the immature organism has certain special properties. Using this notion as a guideline we may trace four theoretical traditions that together include most of the work on early experience: (1) the tradition of developmental biology, (2) the psychiatric and psychoanalytic tradition, (3) the tradition of physiological psychology, and (4) the ethological tradition.

The Tradition of Developmental Biology

Major ideas about the process of biological development have been well reviewed by Hunt (1961) and Kuo (1967). One of the major issues on which most theorists have taken a position has concerned the plasticity or modifiability of the developing organism and the extent to which its phenotype may deviate from its expected genetic pathway or

"ecode" as Waddington (1957) has called it. The logic of Darwinian evolutionary theory coupled with classical Mendelian genetics works better if it can be assumed that the phenotype on which selection acts bears a relatively fixed relation to genotype, so that the "right" individuals—that is, those with the greatest probability of survival—are the ones selected. Certainly, the kinds of characters with which both Darwin and Mendel were concerned, such as flower color, or avian plumage, were stable enough. And even behavioral traits could be viewed in the same way. In his book *Expression of Emotions in Man and Animal* (1872) Darwin attempted to show how the apparently fluid behaviors involved in animal communication were made up of fairly fixed components and that the residuals of these could also be found in human beings. A further step was taken by a number of developmental biologists who attempted to define more precisely the essential building blocks of behavior. Their work, for the most part, was done on lower organisms such as paramecia, stentor, hydra, and planaria. Thus Jacques Loeb (1890) formulated his famous tropism theory, according to which the directed behaviors of many species—for example, the medusa *Tiaropsis indicans*—could be explained in terms of mechanical contraction or extension of musculature in the region of the stimulated surface area. The result of this was an orientation directly toward or away from the source of stimulation, thus rectifying, as it were, the animal's relation with the external world.

In a similar vein, von Uexküll, from his work on the sea urchin, proposed the concept of *reflex*, by which he meant the relatively invariant relation between certain afferent nerves and certain muscles. At least in its broader sense, it was intended to include the behavior of animals without as well as animals with nervous systems—though for the former, von Uexküll preferred to use the term *antitype* rather than reflex (see Jennings, 1915).

Although a radically mechanistic approach to behavior may have been highly compatible with Darwinian theory and was certainly fashionable around the turn of the century, it was not one that fitted all the facts. One of the first to demonstrate this was H. S. Jennings with his extensive studies on a variety of pro-

tozoa, especially amebas, and some of the lower metazoa. He introduced his work by stating

The modifiability of the characteristics of organisms has always been a subject of the greatest importance in biological science. In the processes of behavior we have characteristics that are modifiable with absolute ease. (The general problem) is what lasting changes are producible in organisms by the environment or otherwise, and what are the principles governing such modifications? Perhaps in no other field do we have so favorable an opportunity for the study of this problem, fundamental for all biology, as in behavior (1915, p. VI)

The data obtained by Jennings clearly showed that the lower organisms he studied were not, at least in the usual sense, machines. Their behavior showed variety and spontaneity to an extent not readily encompassed by such notions as tropism and reflex. Thus the behavior of an ameba was clearly adaptive and the rules that governed such adaptiveness "apparently form the fundamental basis of intelligent action. This fundamental basis then clearly exists even in the Protozoa, it is apparently coextensive with life. It is difficult if not impossible to draw a line separating the regulatory behavior of lower organisms from the so-called intelligent behavior of higher ones, the one grades insensibly into the other. From the lowest organism up to man behavior is essentially regulatory in character and what we call intelligence in higher animals is a direct outgrowth of the same laws that give behavior its regulatory character in the Protozoa" (Jennings, 1915, p. 335).

Out of this interest in the modifiability of behavior and the general search for units out of which behavior is built has emerged a great deal of basic empirical work. Some of this has focused primarily on the plasticity problem, some of it primarily on the building-blocks problem. Thus we have a line of research starting mainly with Coghill on *amblystoma*, Kuo on the chick, Barcroft on sheep, and Windle on the cat which has attempted to show just how maturation proceeds (see Carmichael, 1954, Kuo, 1967). Coghill (1929), on the basis of his research findings, put for-

ward the view that specific forms of action come to be individuated out of an initial matrix of total, massive responding. Kuo, on the other hand, working with avian embryos and using more precise techniques, as well as Windle (1940) and others, came to an opposite conclusion: specific movements or reflexes appear first and these form the elements out of which later complex behaviors are constituted (see Carmichael, 1954, Kuo, 1967). Such a disagreement is very difficult to settle empirically since the exact spatial limits of any response are hard to define and, in any case, depend greatly on the intensity and coarseness of the stimulus used to evoke it. However, such descriptive work on developmental sequences is not essentially relevant to our present discussion. The interested reader may consult Carmichael (1954), Kuo (1967), and Aaronson et al. (1966) for reviews of it. Our concern here is rather with the extent to which such early behaviors are modifiable before they assume their stable and crystallized adult forms. The two basic viewpoints about this problem have nicely been summarized by Gottlieb:

One viewpoint holds that behavioral epigenesis is predetermined by invariant organic factors of growth and differentiation (particularly neural maturation), and the other main viewpoint holds that the sequence and outcome of prenatal behavior is probabilistically determined by the critical operation of various endogenous and exogenous stimulative events (Gottlieb, 1966a).

The first position is currently held by Hamburger and his colleagues at Washington University, the second by Kuo, Gottlieb, Schneirla, and others. Whatever the final conclusion may be, there is no doubt that the disagreement has generated a most useful and active line of research. There seem to be strong indications that many embryo motor systems show rhythms or discharges that are called out by spontaneous activity of spinal motor neurons (Hamburger 1962, Alconero, 1965). On the other hand, it is equally true that, under at least some circumstances, exogenous or endogenous stimulation is an important contributing factor to developmental changes. Thus it appears that cardiac beat and amnion con-

tractions produce motility in avian embryos and that there is, in fact, a high correlation between heart rate and frequency of bodily movements (Kuo, 1967). Furthermore, Gottlieb (1966b) has put forward the interesting idea—which he is able to back with some data—that the responsiveness of chicks and ducks to their species call is produced, at least in part, by self-stimulation arising from their own vocalizations at hatch.

It is obvious that this kind of research, even from our very brief account of it, has bearing on the early experience problem, since it deals directly with the plasticity of young systems and the degree to which the developmental course their behavior follows can be altered by environmental influences.

The Psychiatric Tradition

Sigmund Freud was perhaps the first to emphasize the importance of childhood events in determining later behavior. Certainly, other psychologists were engaged in studying children, but not with a view to specifying long-term outcomes resulting from some kind of early treatment. Freud himself, aside from his brief contact with "Little Hans," did not work with children and his construction of the stages of psychosexual development was made on the basis of inference from the reported experiences of his adult patients. Nonetheless, he set the stage for the emergence of a strong tradition of child psychiatry. Prominent in this movement were such workers as Anna Freud, Melanie Klein, and Susan Isaacs, all of whom attempted to validate and extend the formulations of Freud through actual observations of children. Much of this early work, set as it was in the rather cabalistic framework of psychoanalytic theory, tended to receive scant attention from orthodox academic psychology. It was not until the late 1930s and early 1940s that a link between theory and experiment was made by Margaret Ribble (1939, 1944). Her observations carried out on 600 infants seemed to show that adequate "mothering" was a prerequisite to normal development. Deprived of continued, uninterrupted contact with a mother or substitute caretaker, the newborn would often commence to manifest a variety of undesirable and often fatal symptoms collectively described by Ribble as *marasmus*. Both her data

and her theoretical treatment of them were open to many criticisms, which were later forthcoming (Orlansky, 1949; Pinneau, 1950, 1955). Nonetheless, there is no doubt that her basic findings caught the attention both of the public and of professional psychologists and laid the groundwork for several important lines of research. Since we discuss these in more detail in the main body of the chapter, we need only mention them here very briefly.

One basic line of research is simply an attempt to replicate and extend in various directions Ribble's basic data. Studies such as those of Goldfarb (1945a) and Provence and Lipton (1962) on orphanage rearing and those of Spitz (1945) and Bowlby (1952) on separation and lack of mothering are examples. They have, in the main, confirmed the original findings of Ribble. A rather more unexpected line of work, however, was that started with the experiments of Bernstein (1952) and of Weininger (1953) on the effects of "mothering" or "gentling" on the later behavior of young rats. The number of studies devoted to examining this problem has been very great and it is still being examined. Generally, the data have given at least indirect support to the conclusions initially drawn by Ribble. Young rats and mice that are given additional stimulation in moderate amount turn out to be healthier, less emotional, better motivated, and faster learners than those left alone with their mothers. It is curious that the natural mother should turn out to be apparently less than adequate in this respect, but perhaps from the standpoint of survival and adaptation to a lab situation, the kind of "personality" the mother rat or mouse puts into her young is optimal.

For the most part, such experimentation on early stimulation has been of a highly empirical character. Every conceivable aspect of the problem has been examined: the type and intensity of stimulation, the age at which it is administered, the type of behavioral and physiological and biochemical effects that it has, and the characteristics of the animal on which it is imposed. Such studies have certainly resulted in the accumulation of a great deal of information. But it has become very clear that what is needed is some kind of theoretical ordering of such data—conceptualizations that point up the most fruitful directions that future research should follow. As we shall show

later, there are now signs that theorizing is indeed on the increase

The Tradition of Physiological Psychology

A critical problem for physiological psychologists working between the 1920s and 1940s was just how the residuals of learning are laid down in the brain. Karl Lashley, who initially hypothesized a connectionistic view, after many years of experimentation moved to a field-theoretical approach. The greater feasibility of the field-theoretical approach was suggested to him by two sets of data in particular: first, the high positive relation between loss of learning and retention capacity, on the one hand, and amount of loss of brain tissue *independent of locus*, and, second, the *generalizations* that animals were able to make between figures or patterns on which they had been trained to ones they had never seen before. Such facts raised a dilemma and, as Hebb has so clearly pointed out, different theorists took different positions with respect to it. Speaking of two of these, Hebb says

Kohler (1940), for example, starts out with the facts of perceptual generalization, in his theory of cortical fields of force, and then cannot deal with learning. He has no apparent way of avoiding a fatal difficulty about the nature of the trace, its locus and structure

The theory elaborated by Hull (1943), on the other hand, is to be regarded as providing first of all for the stability of learning. It has persistent difficulties with perception (1949, p. 15)

In his work *The Organization of Behavior* from which we have drawn this quote, Hebb attempted a solution to the problem. Perhaps its two most central propositions were as follows

1 The functions of perception and of learning depend on the establishment in the cortex of complex neuronal networks of neurons—or cell assemblies—whose integrity as units is maintained by structural changes occurring at the synapses between them. Such networks may be spread over widely dispersed cortical areas and may involve many alternative pathways

2 Learning during adulthood depends on

the kind of learning that has gone on early in life. The two types of learning have quite different properties, varying with phylogenetic level. Such a skill as learning to perceive, which mainly constitutes primary learning, for example, occurs relatively slowly in higher primates, but rather quickly in lower species, whereas the kind of conceptual learning that goes on at maturity tends to be much more efficient in higher than in lower animals

Hebb's analysis of the mechanisms of the development of learning in animals is one of the most subtle and incisive that has been made. It has been explored experimentally, however, only with respect to its broad emphasis on the importance of early experience for later ability and intelligence. One of the first such studies was done by Hebb himself. He (and his daughters) reared seven rats at home as pets. These were later compared with cage-reared controls on Hebb-Williams maze performance. The free-environment animals were markedly superior, thus demonstrating the importance of early learning in determining adult intellectual ability. This key experiment has served as a paradigm for many subsequent studies, for example, those of Hyman (1952), Forgas and Forgas (1952), Forgas (1954, 1955a, 1955b) on rats and the series on dogs mainly by Thompson, Heron, Melzack, and others (cf. Thompson and Melzack, 1956). Work on the problem still continues (e.g., Schweikert and Collins, 1966; Fuller and Clark, 1966a, 1966b). The results of all this work support, in the main, Hebb's emphasis on the importance of perceptual learning early in life. It is of some interest to note at this point that such experience produces not only clear behavioral but also clear anatomical and biochemical effects in the central nervous system, as shown by the extensive series of Krech, Rosenzweig, and others at Berkeley (cf. Rosenzweig, 1966). Much of the tradition we have outlined has been well reviewed by Hunt (1961) and by Newton and Levine (1967).

The Ethological Tradition

Ethology, a movement mainly among European naturalists, has also produced significant contributions to the study of early

experience Interest in the social structure of animal populations has led naturally to the question of how social attachments between animals—whether these have to do with reproduction, maternal care, or general communication—arise in the first place Konrad Lorenz (1935), one of the initiators of work in the area, put forward the view that, in the case of birds—particularly such precocial species as domestic chickens, ducks, and geese—the hatchling learns in one brief exposure a relatively permanent attachment to an object presented to it at this time, normally the mother Lorenz (1935) called this rather unique form of learning *imprinting* A large volume of work on this topic has since appeared, concerned with such problems as the characteristics of the mother or surrogate that maximize imprinting, the age at which it optimally occurs, the species in which it can be found, its reversibility, ways of measuring it, and its relation to adult behavior, in particular, mate choice Although imprinting may be thought originally to have represented a rather recondite phenomenon of interest only to naturalists, it has clearly come to offer a kind of paradigm for considering all aspects of early socialization and hence to have importance to all psychologists studying learning and development Even these workers dealing directly with children have been influenced by the imprinting studies, for example, Bowlby, who has proposed a theory of infant maternal attachment with a strong ethological bias (Bowlby, 1957), 1958) The concept of imprinting has also been extended in a number of directions to take in territorial and food preferences (see Hess, 1959) The general problem with which these deal, however, is the same—the effects of early experience on later behavior

The preceding overview of the history of work in the area indicates that it is of a very basic nature, drawing together many divergent methodologies and theoretical points of view For this reason, perhaps, it is a difficult task to find a “best way” of reviewing relevant literature We have chosen to order the empirical work mainly according to age level Prior to this we present a short discussion of what properties characterize young living systems and the major methods used in the early experience work We shall end the chapter by presenting some of the theoretical models

that have been put forward to handle the early experience problem

THE NATURE OF YOUNG ORGANISMS

The most obvious characteristic that distinguishes young from adult organisms is age However, by itself, the simple passage of time is an empty variable and has no special implications We must focus instead on those dimensions which change as a function of age and which carry implications for the input, output, and storage characteristics of young organisms For it is these functions that are of major relevance to any real understanding of how early experiential effects operate

A good many such basic developmental variables have been specified by different writers Let us now look at some of these

Differentiation

Differentiation refers, generally, to the transition from a relatively unitary system to one with independent parts At the physiological and morphological levels, we find occurring with age such processes as histogenesis, regionalization, and morphogenesis, whereby qualitative differences in form, structure, and function start to become apparent Thus a zygote becomes a blastula and gradually, through gastrulation, the distinctive ectoderm and endoderm cell layers form, followed eventually by the mesoderm Each of these structures is potentially directed to certain functions such as neural conduction and sensory reception, digestion and metabolism and body support

At the behavioral level the dimension is somewhat more difficult to define On the input side, we may think of it as having to do with the improvement in discriminative ability that occurs with increasing age up to and perhaps beyond maturity Hebb (1949) has suggested that initially the newborn perceives only unities but not identities The speed of learning this second type of task may vary according to the species, lower ones accomplishing it in a much shorter time than higher species, due possibly, according to Hebb (1949, p 124), to a larger association cortex to sensory cortex ratio in the higher This kind of perceptual differentiation is similar to that described by Gibson and Gibson (1955), namely, the progressive increase in corre-

spondence between the input systems and environmental stimulation. It may be contrasted with the so-called "enrichment" theories, which attempt to account for improvement in perceptual discrimination by postulating that cues became "distinctive" by gradually acquiring associations with other stimuli or responses. There are undoubtedly such acquisitions, but it seems likely that they pertain to later rather than early learning in Hebb's terms, and are dependent, in the first instance, on an initial refinement of the perceptual system simply through its exposure to the environment.

In the case of some sensory modes, the motor side must also be implicated. Eye movements and accommodation certainly play a part in the building up of differentiation in the visual system. Haynes, White, and Held (1965), for example, have used the techniques of dynamic retinoscopy to demonstrate that accommodation in the human infant is initially poor. Until around the fourth month, proper focus occurs only for objects at a distance of around 19 cm. Likewise, the work of Kessen (1967) and his associates at Yale suggests that visual scanning plays a critical role in the building up of percepts of shapes such as triangles.

On the motor side as such, differentiation must also occur. It seems convenient, as Thompson (1966, 1968) has attempted to show, to consider this separately from the input side, since this division allows us to think of development in terms of an S-R framework. In any case, common observation suggests that as an organism matures, there is an increasing independence of muscles or muscle groups. Thus the prehension of objects initially involves the whole limb, which is used in a kind of "raking" movement. This gross movement gradually becomes refined into the delicate and economical finger-thumb opposition normally used by an adult, to pick up some object (Halverson, 1931). As with input systems, it is likely that differentiation on the output side may follow a two-stage development, the first being concerned with the laying down of basic skills, the second with the learning of the more refined and complex coordinations often demanded of adults. Thus by the time a child is 10, he usually will have a repertoire of movements sufficient to meet most of the demands his culture may place on

him—for example, crawling, walking, running, climbing, and writing. On these basic skills will be built—with a great deal more rapidity—various special sets of responses such as riding a bicycle, driving a car, ballet, swimming, piano playing, and so forth.

It is probable that differentiation proceeds at different rates in different systems. For example, tactual differentiation may well be considerably ahead of visual or auditory differentiation. Comparing the average rate for input with the average rate for output, it is also likely that the auditory differentiation lags considerably behind the tactual. Thus the young infant's perceptual capacities are considerably closer to the level they will eventually reach than are his motor abilities. By 8 months of age he can discriminate through most of his sensory systems a considerable range of fine differences. But his locomotor, manual, or vocal skills at the same age are very far from the level of refinement they will show at maturity. We shall examine, later in this chapter, some possible consequences of these kinds of postulated differences in respect to rate of differentiation.

Growth

This developmental parameter refers basically to the increments in size or in number of elements that occur in living systems as they change with age (Shock, 1951). Thus most organisms get bigger as they get older. Some level off as they approach sexual maturity, but others, for example, many plant forms and some fish, continue the process until they die. We also find increments in subsystems of the whole, for example, number of fibers in spinal nerves in human beings (cf. Zubek and Solberg, 1954), total brain weight, density of neural and glial cells, cell mitochondria, and quantity of chemical compounds such as ACh, ChE, and GABA per unit mass of tissue (cf. Himwich, 1962). Kasser has suggested (cf. Waddington, 1957), in accordance with the above, that growth produces an increase in the redundancy of a system and that a consequence of this will be a difference between young and mature systems with respect to "buffering" characteristics. Thus it seems reasonable to suppose that the mature organism, because it has more replicated parts serving the same function, will be better able to withstand the impact of some disturbing

environmental event, in the sense that the deviations from the normal level that are allowed will be smaller and the speed of return to normal will be more rapid. It is these kinds of parameters that are at least implicitly referred to when we speak of young systems as being more unstable or more plastic. For example, the response of the newborn rat to water overload is a great deal slower than that of the older animal and it may remain overhydrated for a much longer time after treatment (McCance, 1961, Vesterdal, 1961). The problem of equating the stimulus between age groups is, of course, a formidable one. As Vesterdal (1961) points out, 30 ml of water per kilogram given to an infant weighing 3 kg will be more or less equivalent to an ordinary feeding, but the same ratio administered to an adult weighing 75 kg would amount to 2250 ml—a quantity much above normal intake.

It is rather difficult to think in terms of psychological functions as showing size increments in the same manner as do various physiological systems. But, on the other hand, it is quite sensible to ask about their buffering characteristics as a function of age. It would be very useful to know the extent to which performance in various tasks is disturbed in organisms of different ages. It seems likely, for example, that the same IQ level might be differently susceptible to mild stress in young as against mature organisms. Such a problem—as well as many others like it—is readily testable both in human beings and in lower animals. The work of Campbell and his associates at Princeton (Campbell, 1967, Campbell and Riccio, 1966, Riccio and Campbell, 1966) represents a very good start on this line of research. They have been systematically exploring the response of young as compared with mature animals of different species to a variety of treatments such as cold stress, food deprivation, and electric shock. An example of some of their data is shown in Fig. 1. The major point emerging from the work is clear. Young rats do not behave like adults when subjected to cold stress and consequently it is of great importance to define a treatment imposed not only in physical terms—for example, so many milliamperes of shock stress—but also in terms of the immediate effects they have. It will also be evident that there is some ambiguity in specifying the

Fig. 1 The effects of cold stress (a) Survival time in rats of different ages following immersion in 45°F water (b) Behavioral recovery time as a function of age and duration of immersion

behavior of immature systems in terms of such broad categories as "stability" or "plasticity." They furnish a good theoretical starting point but require close empirical explication. In general, however, we certainly have grounds for believing that, with a physically equivalent stress or environmental event, young systems will be more seriously disturbed than more mature ones, and it is therefore possible that any residual effects will be more important in the sense we have defined this term.

The dimension of growth is one which has heuristic value for the experimental study of development over and above that afforded by

the concept of differentiation. Each has a special meaning and each suggests a particular set of empirical research problems to be tackled.

Organization

This third developmental parameter has to do with the degree to which the subparts that make up a system are interrelated. During the very early stages of life, given reasonably strong stimulation, the organism probably does respond massively as a whole, but whether such behavior can be regarded as random is questionable. It seems more likely that during development, one level of organization replaces a preceding one. Thus in respect to brain function, firing in response to a stimulus may initially occur over widespread areas according to relatively simple mechanical, anatomical, or electrochemical principles. Kohler (1940) viewed the brain as having the properties of a volume conductor, and as long as one is unwilling (as he was) to entertain the possibility of structural changes arising from exposure to environment, which then impose new arrangements on the extant organization, then one is confined to the kinds of parameter Kohler used. Hebb's view (1949) has, of course, been quite different. His notions of cell assembly and phase sequence suggest the continued building up of new organizations which, in their specific aspects, must depend on the unique experience of the individual during his lifetime. Whatever their idiosyncratic features, however, these organizations must effect an increasing coherence in the interactions of the living system with the environment and a shift from stimulus control to control by autonomous central processes.

Although the concept of organization has a certain theoretical appeal, it is not one that so far has lent itself very well to direct empirical study. For one thing, the extent to which organizational changes occur in a system must depend a great deal on the degree of differentiation and the extent of growth in that system. Thus differentiation must continually operate to break up extant organizations, whereas the buffering given by increments in growth may work to preserve them. Even were these somehow constant, organization would still be hard to define in a precise operational way. That this is so is indicated

by the famous so-called Leeper-Young controversy. This centered around the problem of whether emotion had an organizing or disorganizing effect on behavior. Though generating a good deal of lively theorizing, the debate led to very little actual empirical work—a minor study by the senior author being one exception (Thompson and Higgins, 1958).

Whatever the difficulties may be, however, organization does seem to represent a parameter that should be included in any consideration of development, and it is always possible that some ingenious person—particularly if he is experimentally minded—will come up with some way of making the concept empirically useful.

Other Developmental Parameters

The three dimensions we have so far discussed perhaps underlie all others that various workers have attempted to specify. Thus Gesell's (1946) principles of developmental direction, functional asymmetry, reciprocal interweaving, individuating maturation, and self-regulatory fluctuation are descriptive and perhaps derivable from those we have dealt with. At the same time, since they are less abstract, they may offer to the student of development more immediate empirical possibilities. Certainly, they have proven useful in normative studies of the behavior of developing organisms. Our main concern here is whether they have in the past, or may in the future, contribute in any way to research and theorizing on problems of early experience. The answer to the first part of this question must be in the negative. One does not commonly find them discussed as relevant dimensions by workers in this area. The same applies in the case of differentiation, growth, and organization. On the other hand, the latter three notions, in the opinion of the writers, may well have direct value—a point we will attempt to make later on.

We now turn to a consideration of some empirical work on the nature of young organisms and aspects of early life that appear to be critical. This is not intended by any means to be an exhaustive review of all the literature on this topic. Such information can be obtained from several other chapters in this book. All we wish to do is to present a few examples of work which may throw light on

the main problem before us—why early experience is important

CRITICAL ASPECTS OF EARLY EXPERIENCE

Our discussion of the major dimensions of development and the various empirical studies that pertain to them suggests that generally organisms get bigger and better as they mature. They are able to discriminate increasingly finer differences, are able to perform more and different kinds of acts, and become perhaps more strongly buffered against the exigencies of environment. Much the same applies to the subsystems that make up the whole organisms, and each is likely to manifest its own particular rate and pattern of change.

An excellent summary of the kind of changes that have been demonstrated for various physiological, neural, and biochemical functions has been made by Himwich (1962). This is partly reproduced in Table 1. Although such detailed data as these may not immediately aid our understanding of the exact nature of early experience, they do show clearly that the young organism is strikingly different from the adult in very many aspects. They further supply us with useful developmental norms for specific variables against which the

effects of experimental treatments may be compared.

Our major concern here, of course, is with behavior, and how storage that occurs in early life affects various kinds of measurable responses in the adult. Thus the features of early experience that are of most critical concern to us must be the nature of storage at any particular age and the permanence of such storage. It is undeniably difficult to unconfound these two questions, since a clue to the type of storage or learning that predominates at any particular age level is given mainly by some measure taken later that also reflects permanence. However, if we consider that different types of learning—for example, habituation, classical conditioning, and instrumental or operant learning—are distinguishable, then it should be possible not only to assess the overall amount of change that can be produced in organisms of different ages but also to parcel out the relative contributions made to this total change by each type of storage separately. Thus we might find that effects due to habituation are dominant in a very young animal and that these effects are much more marked than any that can be induced through the same type of learning at a later age. A design like this would allow us to ex-

Table 1 Development of Various Physiological and Behavioral Functions in the Brains of Guinea Pigs

	Age from Conception							
	34	39	44	49	54	59	64	69

From Himwich (1962) (modified)

amine separately the two major problems: What is early experience like? And how lasting are its effects? At present, however, almost none of the empirical work done on the topic has been sufficiently precise to yield the relevant data. Thus most of the work of Campbell and his associates (see Campbell, 1967) has been used—as a critical index for drawing conclusions about early memory—a conditioned avoidance response. Data based on this rather complex indicator have suggested that memory is poorer in young than in adult subjects. But it might well be that a more careful dissection of the response into components would yield a different conclusion.

One important line of work should be mentioned in this connection. Lynn (1966) has ably reviewed a large body of Russian literature dealing more specifically with the ontogeny of the so-called orientation reaction in both human young and in the young of various lower species. Several workers have agreed in formulating a three-stage sequence: (1) a stage of autonomic reactions with no behavioral orientation of defensive reaction, (2) a stage involving "passive" defensive reactions and avoidance of stimulation, (3) a stage of normal orientation to stimuli of moderate intensity and defensive reactions to very strong stimulation. In general, most of the studies discussed by Lynn tend to show that habituation in very young animals is slower than in adults. Conditioning, on the other hand, improves with age only up to a point after which it declines again, presumably due to the increasing dominance of the "second signalling system." Some current research by the senior author and his colleagues is aimed precisely at elucidation of this problem. This point will be discussed later in the chapter in the context of theoretical models about early experience.

The notion of *critical* or *sensitive period*, which is often used to explain the lasting effects of certain early experience, also tends to confound problems of storage-mechanism with problems of storage-duration. In its usual meaning, it has involved a particular age level presumably set by maturational factors during which certain responses are more or less irreversibly learned. The most classic example is, of course, imprinting. Thus as a result of exposure to a parent or parent-surrogate at around 12 to 14 hours to posthatch, a young

chick tends later to follow this object or those similar to it, this attachment being less marked if the exposure occurs later or earlier than the critical age. Although it is recognized now that the limits of a critical period are probably not as narrow as originally thought (see Bateson, 1966), it is held by many workers that there are stages during development when certain kinds of experience are most likely to be stored. Such a notion seems, at first sight, to contradict the postulate we suggested earlier: susceptibility to environmental influence decreases linearly as a direct function of age. That it need not do so, however, is indicated by inspection of one model put forward by Hess (1959) to explain the occurrence of a critical period for imprinting. A slightly modified summary of it is presented in Fig. 2a. Note that the existence of a critical period is based on the two separate curves, each of which show a simple relation with age, namely, fear and locomotor ability. These are shown in Figs. 2b and 2c. Fear itself is actually deduced from a further relation—that between age and the ability of the animal to discriminate familiar from unfamiliar aspects of the environment. The intersect of the fear and locomotor curves is taken to be the critical period for imprinting of the following response. Were imprinting measured by other indicators, however, it is likely that the critical period would cover a different age range. Many other variables will be implicated in this also (Bateson, 1966).

The major point we wish to make is that the idea of critical period involves assumptions about the relation of buffering or memory storage to age and also assumptions about what kinds of input and output systems can be regarded as the best indicators of the event under study—for example, in the case of imprinting, the following of some discriminable object by a young chick. It should be noted that the time at which some function emerges and becomes available for involvement in the residual effects of early experience may be difficult to pin down. Thus it is doubtful whether following can be implicated in imprinting if critical exposure occurs before a chick is mobile. On the other hand, many complex adult responses may have precursors in early behavior. A good example of this is the precocial sexual behavior that may be elicited under certain conditions in very

young birds (Andrew, 1963). It is difficult to say when a particular behavior pattern has its onset and how mature it must be before it can be altered in a relatively permanent way by environmental stimulation. At the human level, this has represented a problem of some magnitude. Freud's designation of the ages at which the various stages of psychosexual development occurred has been considerably altered by later workers. The formulations of Melanie Klein (1950), for example, which presuppose, in very young children, attitudes and social perceptions of a most complex kind, certainly seem to strain our credulity. Yet it is quite possible that some precursors of adult social behavior do make their appearance as early as the age of 1 or 2 years and are available for manipulation at this time.

There is one additional consideration concerning the critical aspects of early experience. Whatever treatments are imposed on a young organism, these can have effects only within certain limits set by genotype. This genotype may be permissive or nonpermissive to environmental influences, in the sense that it may allow very small or very large deviations from a projected developmental pathway. As we noted earlier, this notion has been put forward most explicitly by Waddington (1957). His schematic representation of the situation—the epigenetic landscape—is reproduced in Fig. 3. It can be seen here that genes determine the magnitudes and kinds of phenotypic

Fig. 2 Hess' model of the critical period in avian species. (a) The general model. (b) Fear as a function of age. (c) Locomotor capacity as a function of age.

Fig 3 The complex system of interactions underlying the epigenetic landscape

deviations that are possible to the developing organism. Just how genes exert this kind of influence is a matter of conjecture, but the fact that they do so, in respect to behavior, is now well documented by empirical work. We shall consider relevant studies in more detail in the appropriate section.

METHODS OF STUDY

It is perhaps true to say that the degree of methodological precision that has been so far achieved in the study of early experience has not been up to handling properly the kinds of dimensions we have articulated. The usual treatments by which the effects of early experience are tested involve either adding or taking away certain kinds of exogenous stimulation. Thus a rat may be given special handling in addition to that normally given to it by its mother (Denenberg, 1966), or it may be reared in a so-called enriched environment or rat "nursery" of the kind first used by Hymovitch (1952), Forigays and Forigays (1952), and others. Conversely, restriction may be imposed, as in the case of the dog experiments carried out at McGill University

by Thompson and others (Thompson and Melzack, 1956). There has also been a strong interest in the effects of various agents, the exact nature and direction of whose action may be uncertain, for example, drugs or noxious stimulation and stress. A large amount of work has studied the effects in offspring of treatments applied to the mother during pregnancy, for example, experimentally produced anxiety, anoxia, X-irradiation, and a variety of chemical compounds.

The restriction technique has often been applied to the motor side. Spalding's classic experiments (1873) on flying in birds involved the use of this method, as did those of Carmichael (1926) on swimming in *amblystoma*. In Spalding's experiments restriction involved mechanical immobilization of wings, in Carmichael's immobilization of all movement by treating the water with chloretone. Recently, Held and his colleagues (Held et al., 1959, 1961, 1963) have used a modification of it by means of an experimental condition that permitted only passive—not self-produced—movements. Thus kittens were held in a restraining apparatus which moved them through an experimental environment,

simulating the manner in which they would explore it under normal conditions. Presumably, what Held has called *reafferent stimulation* is different in the two cases, and the difference shows up in terms of tests of visual-motor coordination given later. The actual procedure involved, it must be pointed out, is somewhat crude inasmuch as it is extremely difficult to specify exactly all the effects that ensue when an experimenter directs the movements of a subject. Restraining may produce emotional behavior, for example, as well as interfere with practice of sensory-motor skills. But conceptually, such a method represents a step forward, since it involved an attempt to unconfound the effects of restricting input from the effects of limiting kinesthetic feedback arising from voluntary movement. We will return to Held's work later in the chapter.

At the human level, it is very rare to find use made of the type of experimental manipulation that can so readily be carried out with animals. Investigators must look at natural situations which appear to be relevant, for example, nursery schools or other enriching environments, orphanages, lower-class homes, maternal-child separations, and others considered to be restricting or traumatic. The difficulties of control are, of course, formidable and we must therefore be very cautious about the inferences drawn from data based on such methods. Furthermore, because these are naturally occurring situations, they do not lend themselves to precise conceptual or experimental analysis. Thus institutionalization may have effects in respect to the sheer amount of general stimulation it involves, the perceptual richness or complexity it supplies, and finally the kinds of social structure it entails. These factors, which can be fairly well separated in a rat or dog study, are not easily untangled. Nevertheless, in our discussion of the work on early experience in children, we shall attempt as far as possible to achieve such a separation in line with the animal studies, even though it may appear somewhat artificial.

What will be needed in the future is a far greater refinement in the specification of independent and dependent variables. This applies both to animal and human studies. One especially important aspect of this is the careful evaluation of the immediate effects of

whatever treatment is imposed on a young animal. Certainly, it seems reasonable to suppose that the residual effects of some early experiences are more likely to be interpretable in terms of the initial reactions of the subject to the experience rather than in terms of the physical attributes of this variable. The work of Campbell (1967), as mentioned earlier, hits exactly at this problem and will undoubtedly supply much essential baseline information. Likewise much of the current research on human neonates (see Campbell and Thompson, 1968) will be of great value to understanding the problem of early experience and its effects on later behavior.

REVIEW OF STUDIES OF EARLY EXPERIENCE

We now turn to a review of the literature on the problem we are discussing. Though it might have been more desirable to mesh together more closely the animal and human work, this is not easily accomplished. Then traditions, methods, and theoretical frameworks are, for the most part, different. Consequently, we shall consider the two categories separately and attempt at the end of the chapter to indicate possible lines of convergence.

Prenatal Influences

Before the advent of embryology, it used to be thought that almost any event influencing a mother during pregnancy could also influence the unborn fetus. Thus a mother frightened by, say, a dog, could supposedly pass on to her child a phobia of dogs. Such a view was presumably based, at least implicitly, on the assumption that neural connections of some kind existed between the maternal and fetal systems. When embryology was able to establish that no such connections did in fact exist, the idea of maternal impression fell into disrepute. Indeed, there occurred a tendency for medical opinion to swing almost to the diametrically opposed position—that the fetus was almost independent of the mother and would maintain its integrity no matter what environmental contingencies might be imposed on the mother during gestation. It soon became evident, however, that placental exchange between maternal and fetal circulatory systems

was not limited to the transmission of nutritive materials or excretory products but could also carry a great variety of powerful chemical compounds (Page, 1957). These could be either endogenous substances—such as the hormonal products of stress—or exogenous agents taken in by the mother, either accidentally or sometimes for medical reasons.

The embryological evidence suggests, in fact, that the placental system is a highly fluid one. A great range of substances can pass through the intercellular barrier between mother and fetus, its extent depending on the genotype of the animal, the time of gestation, and the quantity and character of the agent involved (Windle, 1940; Flexner and Gellhorn, 1942; Hooker, 1952; Nalbandov, 1958; Page, 1957). In addition, the placenta itself appears to show hormonal activity, secreting ACTH, adrenocorticoids and glucocorticoid substances (Assali and Hammermesz, 1954; Johnson and Haines, 1952; Wiele and Jalet, 1959). Alterations of maternal physiology are known to produce striking changes in the fetus. For example, adrenalectomy of pregnant rats produces fetal adrenal hypertrophy (Ingle and Fisher, 1938; Josimovitch, Hadman, and Deane, 1954; Knobil and Briggs, 1953), cold and ACTH applied to the mother produce a rise in fetal cholesterol level and a large amount of ACTH results in a depletion of adrenal ascorbic acid in the fetus (Jones, Lloyd, and Wvatt, 1953).

The exact mechanisms by which maternal physiological changes are transmitted to and exert an influence on the fetus must be exceedingly complex. However, that these changes can have some influence is certainly clear enough. Since the early work of Gregg (1941) linking abnormalities in the newborn infant, especially blindness, with German measles (rubella virus) in the mother, a great volume of studies has appeared demonstrating teratological effects ensuing from numerous different agents. Poisons, atmospheric changes (hypoxia or anoxia), ionizing radiations, numerous hormones and chemical substances, antibiotics, infectious agents, vitamins in excessive dosages or vitamin deficiencies, and many others have been implicated in such birth defects as cleft lip and cleft palate, absence of limbs, eyes, or tail, hernias, cranial malformations, and many other such gross abnormalities (Kalter and Waikany, 1959;

Montagu, 1961; Fraser, 1958, 1962; Fraser et al., 1953).

Such studies as these are of less importance to us here, however, than those aimed at establishing *behavioral* effects produced by some prenatal treatment—particularly treatments of a psychological nature, for example, emotional stress. The literature covering these kinds of problems does not go back much more than 10 years but has now become fairly extensive. We shall review the highlights of it for human and animal subjects separately.

ANIMAL STUDIES ON BEHAVIORAL EFFECTS OF PRENATAL EXPERIENCE

Chemical Manipulations

An early series of studies was carried out by Hamilton, Harned, and others on the effects on rat offspring of sodium bromide fed to their pregnant mothers in various dosages through a stomach tube. Testing indicated a retardation in learning ability on several learning tasks (Harned, Hamilton, and Bourus, 1940; Hamilton and Harned, 1944). Dosage level apparently was not a variable of major importance. Experimentals tended to be more seizure-prone but showed less emotional elimination in several different situations. The outstanding characteristics of the treated offspring were high aggressiveness and lack of control (Hamilton, 1945). Armistage (1952), using sodium barbitol and pentobarbitol, also found deficits in learning in experimental offspring as compared with controls. However, an improvement in intelligence was claimed by Dispensa and Hornbeck (1941) using prenatal administration of desiccated thyroid hormone. The same workers were able to find no effects from administration of anterior pituitary extract.

Since this early line of work, numerous agents have been screened for their effects on behavioral functions of offspring. Some of these yielding positive results have been alcohol (Vincent, 1958), epinephrine (Thompson and Olian, 1961; Thompson and Goldenberg, 1962; Thompson, Goldenberg, Watson, and Watson, 1963; Thompson, Watson, and Charlesworth, 1962; Young, 1963; Young, 1964; Lieberman, 1963), drugs affecting serotonin activity such as iproniazid, reserpine, 5-HTP, and BAS (Werboff, Gottlieb, Havlena, and Word, 1961), and isocarboxa-

zid (Weiboff, Gottlieb, Dembicki, and Havlena, 1961) Chlorpromazine and meprobamate (Weiboff and Havlena 1962, Weiboff and Kesner, 1963), and labeled chlorpromazine (S^{35} CPZ) (Ordv, Samojewski, Collins, and Rolstein, 1966), a deficiency in such essential substances as phenylalanine (Thompson and Kano, 1965) and protein (Caldwell and Churchill, 1966, 1967) have also been shown to produce alterations in offspring behavior. Profound central nervous system changes can also occur. Thus Zamenhof et al (1966) injected purified bovine pituitary growth hormones into female rats between the seventh and twentieth day of pregnancy. The offspring showed unchanged body weights but significant increases in brain weight, brain DNA content, cortical cell density, and neuron to glial cell ratios. Descriptions of some of the drug studies have been included in the review by Kainofsky (1965).

It is difficult to draw any very precise conclusions about specific drug effects from such work. Almost any compound put into a pregnant animal by any route seems to have effects on a variety of behaviors provided the dosage is sufficient. It is worth pointing out in this connection that very few studies have in fact aimed at demonstrating effects specific to a certain compound. Neither control procedures nor techniques of measurement of the independent variables have been set up in a manner appropriate to this end. Thus the otherwise interesting study by Vincent (1958) showing that alcohol ingested by pregnant mother rats alters emotionality, motivation, and learning of offspring (in both directions depending on dosage level) failed completely to demonstrate that alcohol per se was implicated to the exclusion of other components of the situation—particularly nutritional deficit—that may have been involved. Nor was it made clear that any other chemical substance differing in only a few respects from alcohol in its molecular structure would have different effects, nor was any attempt made to dissect more exactly the components of behavior affected. A study of Thompson and Kano's (1965) aimed at exploring some of these problems. It attempted specifically to examine the effects of phenylalanine overload in pregnant rats both on the relevant metabolic system in offspring—that is, the phenylalan-

ine hydrolase system—and also on emotional as distinct from intellectual behavior. It is significant that the changes found were not specific to this biochemical system and were mainly emotional rather than intellectual in character. Such results seem to indicate that we can hope for very little precision in this field, and it may well be that it is the stress components of drug administration rather than their chemical characteristics that produce an effect. We will return to this point shortly.

X-Irradiation

Literature on some of the neural and behavioral effects of ionizing radiation have been reviewed by Fuichtgott (1963), Weiboff (1964), and Garcia, Kimeldorf and Hunt (1961). Levinson (1952), one of the first experimenters in this field, irradiated pregnant rats with 300 to 600 r at days 11, 13, 15, 17, or 19 of gestation. The learning of offspring on a Lashley III maze was significantly decreased. Since numbers in the subgroups were very small, no analysis could be made of dosage or drugs effects. Fuichtgott and his colleagues (1958a, 1958b, 1958c) later attempted to replicate and extend Levinson's findings. They found a suggestion that the earlier the age, the lower the dosage necessary to produce learning deficits. Thus at days 14 and 15 of gestation, 100 r was effective, but at 18 days neonatally, only subjects receiving 300 r showed changes. Locomotor coordination, on the other hand, was more easily altered with low dosage levels at later stages of gestation. Fetal irradiation was shown to result in increased general activity, longer cage-emergence latencies (time taken to leave home cage and emerge into a strange environment), and increased emotional defecation. The authors interpreted this to mean that irradiation during early development affects fearfulness primarily.

Work in other laboratories has to some extent borne out these general conclusions with some modifications. Weiboff, Bioeder, Havlena, and Sikov (1961) have demonstrated that radiation at any level between 25 and 100 r could alter threshold in offspring to seizures (bell plus metrazol). Radiation during early gestation produced an *increase* in threshold, later in gestation a *decrease* in threshold. In another experiment, Weiboff, Havlena, and Sikov (1962) were able to show that changes

in emotionality and also in maze-learning ability ensued on administration of low dosages of radiation well below those used by Furchtgott et al on their animals. They expressed disagreement with the general proposition that emotionality was always increased and learning ability decreased as a result of fetal radiation. In fact, some of their animals showed exactly opposite effects. A later study by Werboff, Havlena, and Sikov (1963) showed that the threshold for behavioral effects was probably between 15 and 25 r, at least after the fifth day of gestation. It was recognized by Werboff et al that before this time even smaller dosages might have effects. This notion was also put forward experimentally by Luchsinger (1963) and by Kaplan, Rugh, and White (1963). Thus there appears to be an interaction between dosage level and age of organism on which it is imposed.

The extent of exposure to radiation is an additional factor. Some Russian investigators, Piontkovskiy and Semagin (1963), found that only 1 r administered between days 1 and 20 of gestation led to a slower rate of formation and stabilization of simple stereotyped conditioned responses. Interestingly enough, this treatment also produced a significant reduction of thickness of frontal cortex. A rather thorough study by Fowler et al (1962) using 150 r of X-radiation administered on day 13 to 14 of gestation demonstrated that treated fetuses subsequently showed decreased ability on the more difficult problems of the Hebb-Williams maze test and decreased open-field adaptiveness. Various neurological abnormalities in neocortex and in various subcortical structures were also reported (Fowler et al, 1962; Hicks et al, 1959). Quite a large volume of work has been done on the problem in the Soviet Union. Some of this has been reviewed in a conference proceedings edited by Werboff (1963).

Atmospheric Changes

Little has been done on the behavioral effects in offspring of maternal exposure to this variable. Becker and Donnell (1952) showed deficits in the learning by guinea pigs of a complex task as a result of severe asphyxia at birth. Experimental animals were markedly less active and gave the appearance of being less inquisitive and more apathetic and lethargic than controls.

One of the more extensive studies on the topic was carried out by Meier, Bunch, Nolan, and Scheidler (1960) at Washington University. They examined the effects of natal anoxia on young rats and kittens and of prenatal anoxia at various gestation ages on rats. They found that 60 min oxygen deprivation at birth (291% equivalent oxygen) produced deficits in learning ability in rats and 30 min deprivation decreased responsiveness of kittens in a puzzle-box situation and more "stereotyped" modes of solution in a discrimination task. Finally, a 2-hour exposure of pregnant female rats to 621% equivalent oxygen had significant effects on learning ability of offspring. Treatment early in gestation *facilitated* maze performance, treatment late in gestation *hindered* it. The authors speculated that two factors might be involved as target functions at different stages of development. One of these was presumably vulnerable early in gestation and the impact of a treatment on it would improve performance. The other would be vulnerable at a later stage and its response to treatment would reduce learning ability. In view of Furchtgott's rather similar data, which we discussed above, this seems like a reasonable idea.

Just how anoxia (and X-radiation) have their effects has been the subject of a controversy. Some investigators have felt that they are the result of a direct insult to the fetus, others that they come about indirectly through maternal influence. This problem has been reviewed by Meier (1962).

General Stress

We have already noted that almost any kind of treatment imposed on the developing fetus can have effects, and any differences appearing between specific agents probably relate to the general stress or effects these agents have rather than to their intrinsic characteristics. It is significant that, in fact, different injection procedures (subcutaneous versus intraperitoneal) or different placebos (saline versus distilled water) can also produce behavioral changes of an order as great as that produced by various chemical compounds (Havlena and Werboff, 1963a). Consequently, there is every reason to believe that any treatment that can produce a stress response in a pregnant female and in the fetus is likely to leave residues that will later be-

come manifest in various forms of behavior. A fairly extensive line of work has been concerned with exactly this problem.

The first attempt to study the effects of maternal stress during pregnancy on emotional behavior of offspring was initiated by Thompson (1957). Female rats were just trained to avoid shock at the sound of a buzzer by opening a door and running to the safe side of a two-compartment box. It was assumed that the habit was maintained by an acquired anxiety drive. After reaching a criterion level of responding they were mated together with control females to a common sample of males. As soon as they were pregnant, the experimental females were given three daily exposures to the conditioned anxiety-evoking signal but were denied the opportunity to perform the instrumental response that had up to then brought about anxiety reduction. At parturition, some of the offspring were left with their natural mothers, and others were fostered either to different mothers of the same or of a different treatment group. Testing was carried out on two ages using two measures of emotionality. Main results are shown in Fig. 4. It is clear that anxiety during pregnancy does indeed alter offspring behavior, in this case the change being in the direction of increased emotionality or fearfulness.

These results have since been replicated in the main by a number of investigators (Doyle and Yule, 1959; Hockman, 1961; Ader and Belfer, 1962; Thompson, Charlesworth, and

Watson, 1962; Thompson and Quimby, 1964). It is noteworthy that direction of effects is not always toward increased emotionality but sometimes the opposite (Thompson and Quimby, 1964). Furthermore, fostering may interact with prenatal experience in complex ways (Hockman, 1961; Thompson, Watson, and Charlesworth, 1962) either to facilitate or inhibit the effects of the latter. Morita (1965) used fear conditioning prior to pregnancy but with radiant heat rather than shock as a UCS. He found that behavior decrements (open-field and water T-maze) were produced in many by stress in the second half of pregnancy. A higher level of prenatal stress produced greater behavioral deficit. Fertility and viability were also affected.

If conditioned anxiety can alter offspring behavior it might be expected that any kind of stress will do the same. This indeed seems to be the case. Various forms of physical stress have been examined. Offspring from mother rats subjected to audiogenic seizures during pregnancy show changes in behavior, as demonstrated by Thompson and Sontag (1956). Weir and DeFries (1964) and DeFries (1964) used swimming in water 25°C for 3 min, 3 min exposure to a "tilt box," and 2 min in a brightly lit open field. These conditions were imposed on two strains of mice daily during gestation. The usual kinds of change in emotionality were found, although their extent and direction varied with genotype and postnatal treatment. Crowding of pregnant mice produces lowered activity, slowness of responding, and reduced defecation in their young tested at 30 and 100 days of age (Keeley, 1962). Extra handling given to mother rats during gestation reduces emotionality in experimental offspring (Ader and Conklin, 1963). A greater susceptibility to gastric erosion follows immobilization stress, especially in female offspring (Ader and Plaut, 1967). The imposed stress does not necessarily have to occur during pregnancy. Thus Denenberg and Whimbey (1963a) have demonstrated that the offspring of female rats handled in infancy show significant decreases in emotional behavior (open-field activity and defecation) as compared with controls from females not manipulated in infancy. Ressler's studies (1966a, 1966b) demonstrate essentially the same conclusion.

Fig. 4 Open-field activity levels in rat offspring from mothers made anxious during pregnancy (Es) and normal mothers (Cs). Low activity is taken to mean high emotionality (Thompson, 1957).

Fig 5 Effects on behavior of rat offspring of (a) X-irradiation administered to their mothers early or late in gestation (b) Two levels of anxiety-stress administered to their mothers during the whole of gestation H = high anxiety, L = low anxiety, C = control (Thompson and Qunby, 1964)

General Conclusions

Three points of special interest should be noted here. First, changes that ensue from some prenatal stress may vary in extent and direction depending on amount of stress and the age at which stress is imposed. These two points are illustrated in Fig 5 based on Werboff et al (1962) and Thompson and

Qunby (1964). In the former, intelligence is increased over controls by radiation given early in pregnancy, reduced if given late in pregnancy. In the second study, emotionality as measured by activity level tends to be increased as a direct function of pregnancy anxiety.

Such bidirectionality is possibly a function of the sequencing of test procedure and how often tests are given. Thus DeFries and Weir (1964) showed that the initial test (open-field activity) given to treated and untreated offspring may bias the results of a later testing. Groups that were tested at 120 days of age showed only characteristics exactly opposite those which had had a prior test at 40 days. Experimental animals given the early plus the late test were more emotional than controls. Those having only the single, late test were less emotional. This finding raises some most interesting theoretical issues, which we shall discuss later on.

A second point relates to the problem of whether specific stressors can have specific effects. We have already suggested that this seems unlikely. However, Joffe (1965), using a "conflict" stress rather than stressors of the kind described above, found no effects on emotionality but a reduction in Hebb-Williams maze performance. Whether the effects of conflict on the mother have to do only with intelligence in the offspring seems, however, very doubtful. Most maze tests involve emo-

tional and temperamental components and it is possible that these influenced error scores in learning without showing up in the other tests

A third important point has been made by Webster (1967), who suggested that the effects of prenatal stress may often result from the alteration of the nutritional status of the animal on which the stress is imposed. He was, in fact, able to demonstrate that deficits in maze learning of offspring were strongly correlated with weight loss of mothers during treatment. This is not an unexpected finding, since food deprivation has clear and dramatic teratogenic effects in some breeds of mice (Runner and Miller, 1956), and hence it might certainly be expected to exert effects on behavior. But since it is a factor that is very seldom controlled in behavior studies, the emphasis given to it by Webster is very worthwhile.

HUMAN DATA

Work on the problem of prenatal influences involving human beings has been less convincing than that done with animals. In fact, it is only the positive findings coming out of the animal studies that give credibility to the conclusions drawn concerning human beings. Generally the work has been epidemiological and retrospective in nature. That is to say, large samples of children having some kind of abnormality are located and the pregnancy records of their mothers are assessed. The positive relationships that are often established, however, are correlational, and casual by inference only. Since proper control procedures, especially for genetic and postnatal variables, are seldom carried out, this inferential step has usually been a very large one.

Sontag (1941) was one of the first to examine the problem. He suggested that the chemical substances which appear in a mother's blood during emotional stress and which are transmitted to her child may have adverse effects on that child. He reports that fetal bodily movements are markedly increased when mothers undergo stress. The effects of brief maternal stress on fetal movement endure for several hours, while prolonged maternal stress produces concomitant increased activity in the fetus throughout the whole stress period. In addition, infants born to dis-

turbed mothers continue to have high activity levels after birth. They are irritable and may often have feeding, sleeping, and gastrointestinal disturbances. Early and prolonged stress seems to have more damaging effects than stress occurring later in pregnancy (Gebhard et al., 1958; Wallin and Rilev, 1950).

According to Sontag, then, mothers who are emotionally upset during their pregnancies may give birth to neurotic offspring because of the unsatisfactory fetal environment they have provided them. Any conclusions about "blood-borne anxieties," however, must be modified by the knowledge that mothers who are under stress when they are pregnant may also continue to be anxious and emotionally upset after they have given birth. Thus some, much, or all of their infants' distress may be due to tense mother-child relations following birth. Colic, characterized by excessive crying and symptoms of acute distress in the digestive tract, has also been attributed to maternal tenseness and anxiety during pregnancy. Mothers of colicky babies seem to be less accepting of their roles as mothers, more concerned about their ability to care for their child, and less secure and in harmony with other people than mothers of noncolicky babies (Stewart et al., 1954; Lakin, 1957). Again, however, we have no reason to assume that anxiety during pregnancy is the causal factor in the production of colic. It may be that the tenseness a mother displays in caring for her child after birth is the important thing in its development. Again, it is not unlikely that a mother would become anxious and have doubts about her ability as a mother *because* her child was acutely upset no matter what she did to try and comfort him.

Other variables, besides maternal emotional stress, affect the welfare of a developing fetus. The use by the mother of certain drugs may cause various kinds of damage to the fetus. Thalidomide, for example, is responsible for malformation of the limbs when used early in pregnancy. It interferes with growth of the long bones of the arm, with the result that the fetus' hands extend almost directly from its shoulders. The legs are less affected, but do show a similar distortion in growth (Tausig, 1962). Large doses of quinine, used in the treatment of malaria, often cause deafness because of their effect on the fetal inner ear. Maternal use of narcotics may produce

temporary dysfunctioning in the fetus. Montagu (1950) suggests that heavy use of pain-killing drugs prior to delivery may affect the oxygen supply to the fetal brain and even lead to permanent brain damage with resulting intellectual impairment. Although there is no evidence that maternal smoking has enduring effects on fetal development, Sontag and Wallace (1935) do report that the fetal heart rate often accelerates following the mother's smoking. There is little evidence pertaining to the effect on the fetus of a mother's use of alcohol.

Fetal infection from maternal disease is infrequent, although in some rare cases infants have been born with mumps, measles, chickenpox, or smallpox transmitted from the mother (Goodpasture, 1942). Maternal syphilis, however, can have a damaging effect on the fetus. The child of a syphilitic mother, if it avoids abortion, miscarriage, or stillbirth, may be born weak, deformed, or mentally deficient (Montagu, 1959). It can also manifest the symptoms of syphilis, although these may not appear until many years after birth. Rubella (German measles), contracted by a mother in her first two or three months of pregnancy, is highly likely to produce a variety of congenital abnormalities including deaf mutism, cardiac lesions, and microcephaly (Swan and Tostevin, 1946). This diversity of abnormalities is explained by the fact that during early stages of development several organs are in the process of differentiation and hence susceptible to injury. Pronounced thyroid deficiency results in cretinism, characterized by impaired intellectual functioning, failure of bones and cartilage to develop, a protruding abdomen, and rough, coarse skin.

Small amounts of X-irradiation in the maternal pelvic region do not appear to damage the fetus. Murphy (1929), however, reports that large doses of therapeutic X-irradiation given to mothers during pregnancy do result in physical and mental abnormalities in offspring, including intellectual retardation, physical deformation, and blindness. In a study of the effects of exposure to atomic attack, Neel (1953) reports a great increase in stillbirths, abortions, and malformations among infants born to mothers who had been in Nagasaki and Hiroshima during atomic attack.

Because the unborn child's nourishment comes from the maternal bloodstream through

the placenta, nutritional deficiencies in the mother, especially severe ones, will be reflected in fetal development. Hepner (1958) and Knoblock and Pasamanick (1958) report a greater incidence of mental deficiency and physical abnormality (e.g., general physical weakness, epilepsy, rickets, cerebral palsy) in children whose mothers have experienced serious malnutrition during pregnancy. Similarly, Pasamanick, Lilienfeld, and their colleagues (Pasamanick and Knoblock, 1961, Lilienfeld et al., 1955) have claimed a relationship between incidence of complications during the mother's pregnancy and various behavioral changes in the offspring, including tics, speech defects, and behavior disorders. Stott (1957, 1958), on the basis of data obtained mostly from retarded or mongoloid children, has attempted to relate causally pregnancy stress, early illness, malformation, and "unforthcomingness," a trait assessed by the Bristol social adjustment guides and defined in terms of a lack of assertiveness, "will and effectiveness." In these studies, it must be pointed out that control of other variables was loose and the samples atypical. Furthermore, it is now known that mongolism or Down's syndrome is due to a chromosomal anomaly. Consequently, we must view the conclusions with some skepticism.

Prolonged malnutrition of the mother is one of the most common causes of fetal and neonatal death and of incurable damage to infants (Antonov, 1947, Smith, 1947, Stearns, 1958). In an experimental study of maternal diet, Ebbs, Tisdall, and Scott (1942) supplemented the diet of a group of mothers who had been receiving a nutritionally inadequate diet for the first four or five months of their pregnancies. The diet supplement continued until five weeks after their babies were born. Mothers in a control group continued to eat nutritionally inadequate food for their whole pregnancy. There was a much smaller incidence of miscarriages, premature births, and stillbirths in the experimental than in the control group. In addition, babies born to mothers in the experimental group were healthier during their first six months.

Postnatal Influences

The largest volume of work on the early experience problem has been directed to demonstrating the effects on later behavior of dif-

ferent kinds of treatment administered to a young organism during the critical phases of its postnatal development. Like the studies on prenatal influences described above, work here has also been strongly empirical in character. Various sectors of research in the area have been reviewed Beach and Jaynes (1954), King (1958), Thompson (1960, 1966, 1968), Denenberg (1962a, 1966), Hunt (1961), Sluckin (1964), Casler (1961), and by the various contributors to Stevenson, Hess, and Rheingold (1967) and to Newton and Levine (1967). Since the number of studies done over the last 20 years probably amounts to close to 1000, we shall not attempt to provide a complete review of them. In view of their largely parametric style, this would, in any case, be an almost unmanageable task. Instead, we present some of the major conclusions that seem to have emerged regarding the types of variables that are involved in early experience and the kinds of effects they produce.

ANIMAL STUDIES

General Massive Stimulation

As we indicated earlier, an interesting line of work on animals grew directly out of Ribble's observation that "mothering" had an important role in promoting the healthy development of human neonates. Initial experiments carried out on rats by Bernstein (1952) and Weininger (1953, 1956) involved a so-called "gentling" procedure—that is, the handling of young rats for certain durations of time—and the later behavioral assessment of these animals together with "nongentled" controls. Results were quite clear-cut and dramatic. They showed, in essence, that such early manipulation produced large decreases in emotionality and an increase in exploratory activity and also alterations of a physiological nature, for example, a smaller enlargement of adrenals in response to a severe adulthood stress such as immobilization coupled with complete food and water deprivation (Weininger, 1953). Handled animals were more stress resistant than nonhandled rats.

From the early 1950s, studies have proliferated at an exponential rate. All conceivable variations of the problem have been examined, but it still seems true that really fruitful theoretical directions and solid em-

pirical generalizations which are not so broad as to be trivial have failed to emerge in any clear fashion. We shall summarize material under two main headings: treatments and effects, and essential parameters.

Treatments and Effects It was supposed in the initial phases of work on the effects of early manipulation that being "gentle" to a young animal was a critical aspect of the treatment (Bernstein, 1952; Weininger, 1953). This assumption was based at least in part on the work of Ribble (1944) cited earlier, in which the notion "love object" had been explicitly stressed. What subsequent studies clearly showed, however, was that not only the "gentleness" with which handling was carried out irrelevant to the effects produced (see, e.g., Eells, 1961), but also that handling itself—in the sense of experimenter-contact—was also not a necessary condition. Thus a noxious stimulation such as electric shock (Levine, 1956; Salama and Hunt, 1964) or shaking or moving the living cages of the animals (Levine, 1959) produces behavioral changes indistinguishable from those produced by handling. The same applies to the many other types of treatment that have been used, including level of ambient stimulation (Denenberg et al., 1966; McMichael, 1966), husbandry conditions, for example, procedures for cage maintenance and mode of feeding (Denenberg and Whimbever, 1963; Ader, 1965), consistency or roughness of handling (Eells, 1961), temperature alterations including cooling (Schaefer, 1963; Schaefer et al., 1962; Hutchings, 1963) or heating (Kline and Denenberg, unpublished, cf. Denenberg, 1966; Werboff and Havlena, 1963), and auditory or vibratory stimulation (Lindzey et al., 1960, 1963; Winston, 1963).

Bovard (1958) attempted to distinguish two stimulation procedures. Type I, involving actual stroking of an animal as in the Weininger and Bernstein studies, Type II, in which the animal is simply removed from its home cage to a different environment and then replaced after a period of time. However, since these procedures have much the same effects, as Bovard points out, the distinction really is of questionable value.

Social conditions of rearing also appear to be important. Ottinger et al. (1963) have shown that multiple mothering—rotation of a litter from a real to a foster mother—produces

increases in offspring emotionality, as does also the level of maternal emotionality. Some workers have suggested that litter size can be an important variable. Seitz, in two studies (1954, 1958), showed that animals reared in large litters tended to be more emotional than those raised in small litters, apparently due to the greater amount of individual attention accorded to a pup by the mother when it does not have to contend with many others as well. These general findings were confirmed by Carlson (1961) but not by Broadhurst and Levine (1963). The discrepancy may well have been due, as suggested by Denenberg (1966), to the genetic difference between the strains involved in their studies. Certainly, some genotypes are better "buffered" than others and less readily show effects as a consequence of minor environmental manipulations.

Mixing of genotypes in a litter apparently has effects on later behavior. Ressler (1962) showed that BALB/C mice reared by foster mothers of the same or of a different strain (C57BL/10) elicit more maternal handling than if reared by their own mothers. The same does not apply in the case of C57BL pups, however. Reading (1966) has further shown that the later behavior of these same two strains is affected, compared to controls, by alien maternal rearing, it being apparently pulled away from that predicted by their genotype in the direction of that of the alien strain. Work on the effects of interspecies rather than interstrain rearing has been carried out by Denenberg and his colleagues (Denenberg et al., 1964, 1966, Hudgens et al., 1967). They have shown that mouse pups can be quite satisfactorily reared by rat mothers. Mice so reared turned out to be different from mouse-reared mice, the former showing greater weights at weaning and at 48 days and also less aggressiveness. It was also true in the Hudgens study, however, that mortality rate through weaning was approximately 75% for the animals fostered to rat mothers as compared with about 25% for mice reared by mothers of their own species. Hudgens and his colleagues argue that this selective bias is not serious. But in the opinion of the writers they do not make a convincing case for ignoring it, though it is admittedly difficult to assess properly the co-

gency of their arguments on the basis of their report.

The general conclusion that may be derived from all these studies is that treatment effects are nonspecific and that any differences in kind or magnitude are due not to any special features of a treatment but rather to variation in such fundamental parameters as its intensity and the age at which it is administered. An important qualification to this notion should also be made: the specificity of the linkage between effects (however general they may be) and some treatment probably increases with age. In other words, shocking a neonatal rat is likely to result in an animal which shows, in adulthood, a change in level of emotional responsiveness to any kind of stimulus situation. Shocking a postweanling rat, on the other hand, may produce changes that are similar in kind and extent but linked to the context in which the original experience occurred. Gauron (1964) has emphasized the idea of trauma-specificity and has presented relevant evidence. He found that rats exposed early in life to a water stress (immersion) performed poorly in a water-escape maze later in life, but behaved similarly to controls in an avoidance learning situation. It is quite possible, of course, that the difference was due not to the "trauma-relevance" of the tests but rather to the relative amount of stress each entailed. Consequently, Gauron's thesis cannot be regarded as proved. The senior author has put forward a similar view (to be discussed later), but one that postulates a dependence of degree of trauma-specificity on age and the accompanying differentiation of input systems. Brookshire, Littman, and Stewart (1961), in their distinction between three residues of early trauma—"pure shock effect," "acquired fear," and "instrumental habit"—seem to be making a similar point. They refer to the possibility that a trauma may have three kinds of effect: one mediated purely by its action as a stressor, a second mediated by the generalization to other cues of the fear response it produces, and a third mediated by the "shaping" it can exert on different operants.

An important study by Lindholm (1962) bears on these distinctions. He was able to show that with a certain age group of rats (20 to 30 days), noxious stimulation could

have the paradoxical effect of establishing a conditioned fear to a specific but of reducing fear in general. It is clear from this result that the category of "emotionality" may be too broad to be always useful. Finally, Henderson (1965) has suggested that the mechanism responsible for later effects on emotionality—especially as measured by activity scores—may relate to shaping of operant movement responses by the reinforcement involved in any stress rather than to the stimulation effects it has. A study designed by this worker to test this possibility yielded negative results (Henderson, 1966b). Thus shaping does not seem to be an important factor at a very young age at least. Again, however, it is still possible that such learning is involved, though to such a small extent that its effects are not readily discernible by the tests conventionally used.

As the preceding discussion has indicated, the major target systems for early stimulation appear to be those connected with emotional behavior. Changes show up on such variables as open-field activity level of defecation, avoidance learning, shock escape learning, various "time of emergence" tests, responsiveness to stress including survival time, different measures of exploratory behavior, social behavior, dominance, and water-maze learning (see Denenberg, 1966, Thompson, 1966, 1968). On the physiological side, effects have been demonstrated with respect to general growth rate (Levine, 1961), adrenal size (Weininger, 1956), adrenal ascorbic acid activity (Levine et al., 1958, 1959), formation of gastric erosions (Ader, 1965), leukocyte changes in response to stress (Levine, 1961), plasma corticosterone level (Denenberg et al., 1967, Halmeyer et al., 1967), subcortical cholinesterase activity (Tapp and Markowitz, 1963), and survival time in response to carcinoma implantation (Newton et al., 1962). Such results as these have led some if not most workers to the conclusion that early manipulations of most kinds do not *directly* affect intellectual functions. Denenberg and Morton (1962b) have put forward this view on the basis of their data showing no effects of early preweaning handling on Hebb-Williams maze performance. Their conclusion is supported by Schaefer (1963) and by Winston (1963). It is still true, of course, that most

tests of intelligence in animals involve components of emotionality and motivation. Consequently, unless these are parcelled out by some procedure (e.g., extensive pretraining) they will inevitably show up in tests of exploration and maze learning. Meyers (1962), for example, has reported effects on the tendency of animals to "explore" an alley, but it is very doubtful if his measures reflect anything beyond what is commonly thought of as emotionality or responsiveness to stress. DeNelsky and Denenberg (1967), on the other hand, have claimed to have been able to pull apart experimentally factors of emotionality from factors of exploration and curiosity. They found that handling produced rats that were less emotional (as measured by defecation and general activity level) but more exploratory in the sense that their activity increased in proportion to the amount of "complexity" (tactical variation) offered by the environment. Nonhandled controls showed decreasing activity with increasing environmental variation. A similar finding was reported earlier by Halliday (1966).

Relevant Parameters If it is granted that the behavior most affected by massive stimulation early in life have to do with emotion or arousal level, three important questions may still be asked: (1) Is it possible to articulate more precisely this rather broad category? (2) What can be said about the direction of changes produced? (3) To what extent is the "earliness" of the stimulation a necessary condition for producing lasting changes?

In response to the first problem, not a great deal can be said. The only real attempt at dimensional analysis of emotionality has been made by Whimbeev and Denenberg (1966), who factor analyzed results obtained on 23 tests of early stimulation effects. Three of the six obtained factors were reported as being clearly identifiable: "emotional reactivity," "consumption-elimination" and "field exploration." Although the rationale of the study was a good one, such results are not very informative. In the opinion of the writers, experimental rather than statistical dissection of the behaviors involved in early experience effects will be more likely to yield fruitful conclusions. The studies of DeNelsky and Halliday cited above appear to be oriented in this direction.

(a)

(b)

Fig 6 (a) Number of avoidance responses in adult mice as a function of amount and age of infantile handling (b) Number of avoidance responses in adult mice as a function of shock level used during training and amount of shock stimulation received at 25 days of age

Data in regard to the second question are more definitive. Denenberg (1959) and Denenberg and Karas (1960) were among the first to demonstrate emotional reactivity may be either increased or decreased depending on intensity of stimulation. Their main results for avoidance learning in mice are shown in Fig 6. Additional data bearing on this point have been provided by Denenberg (1962b) using rats, his measures being weight, avoidance learning, and survival time following complete deprivation. Again, the relation between these variables and number of days of handling was generally curvilinear in form.

Numerous other investigators, notably Levine, Chevalier, and Korchin (1956), Meyers (1965), and Henderson (1964), have reported similar results. The data of Meyers' (1965) are summarized in Fig 7.

Besides duration and physical level of stimulation, frequency and the extent of massing or spacing of stress (Karas and Denenberg, 1961, Henderson, 1966c) are also important variables, presumably because these relate directly to intensity.

It should be obvious, of course, that effects will be unidirectional if only a limited intensity range is studied. Thus Denenberg and Haltmeyer (1967) showed that plasma corticosterone level assayed in rats following shock in adulthood at either of two levels decreased as a function of number of days of handling. These data are presented in Fig 8. Whether the curves would in fact inflect if more or less stimulation were imposed is unknown. The authors take the position that they would not and that this physiological variable bears a *monotonic* relation to level of infantile stimulation. Although such a point of view appears to be at odds with the behavioral data cited above, it need not be, provided one assumes that a certain score on a test (e.g., avoidance learning) can occur for quite different reasons, thus an animal can perform poorly because it

Fig 7 A U-shaped function relating exploratory activity and degrees of intensity of stimulation (Meyers, 1965)

Fig 8 Mean plasma corticosterone response as a function of preassay shock level and amount of prior stimulation (handling) (Denenberg and Haltmeyer, 1967)

is very *emotional* or, conversely, because it is very *unemotional*. A fuller statement of this notion has been made by Denenberg (1964) and will be discussed later in more detail.

Age is another parameter showing somewhat the same relation to direction of effects. This point has been demonstrated by Bell et al (1962, 1963) and by Henderson (1964). Figure 9 summarizes the results of the second of these investigators relating the effects of shock or handling at each of seven ages to defecation and avoidance-learning scores measured at 60 and 85 days of age, respectively. The age effect is very clear empirically speaking, though the theoretical reason for it is less obvious. Furthermore, it is not certain to what extent such a sensitive period is liable to shift according to the level of stimulation used. When both age and manipulation intensity are varied at the same time, results of manipulation intensity tends to overwhelm those of age (Denenberg and Kline, 1964). For this reason, Denenberg (1962) has argued that a search for critical periods in relation to early stimulation effects may be a fruitless task.

The final question concerns the extent to which the kinds of change discussed are dependent on stimulation early in life and whether they can as readily be produced in adult animals. It is usually assumed that the

immaturity of the animal is an important if not a necessary condition for producing drastic alterations, but few studies have explicitly shown this to be so. In fact, some of those investigators who have utilized adult control groups, for example, Dolittle and Meade (1957), Ader (1959), and Brookshue, Littman, and Stewart (1961), have shown that prior experience is certainly important, but not exclusively early experience. Doty and Doty (1967) used five age groups—3-, 15-, 250-, 400-, and 600-day-old animals—to study the effects of handling on behavior. Their results indicated that all age levels were affected and only temporarily. Age was a major variable determining activity level, regardless of extrastimulation treatment.

On the other hand, other investigators have obtained positive results. Levine (1956), for

Fig 9 (a) Open-field defecation as a function of age of stimulation (shock) (Henderson, 1964) (b) Trials to criterion in avoidance responding in adult mice as a function of age of stimulation (shock)

example, used a group of rats handled in infancy, one not handled, and an adult-handled group. He found that the early treated animals were the least emotional, the controls the most emotional, and the adult-handled rats in between. These conclusions are in general agreement with data reported earlier by Hunt (1941) and Wolf (1943). As matters stand, then, the problem can still be considered to be not completely settled. Before it can be, it will certainly be necessary to dissect more closely the experience that is being put in, since it is quite likely that some types of storage occur more readily in young and other types more readily in older animals. Campbell (1967) has argued, on the basis of a good deal of data, that adults do, in fact, retain conditioned avoidance responses better than young rats. But it would be a mistake to suppose that the same necessarily applies to the kind of changes in emotionality or reactivity brought about by stimulation. Much more work needs to be done on this interesting question.

Special Treatments

Several attempts have been made to establish the effects of quite specific types of early stimulation. Thus Soskin (1963) raised rats in a vibrating environment between either 1 and 21, 22 and 43, or 44 and 65 days of age. None of the experimental groups turned out to prefer a vibrating environment when tested in adulthood, but the 1 to 21 day group showed significantly less avoidance of the vibration over a stable environment when given a choice.

Marr and Gardner (1965) studied the effects of early exposure to particular olfactory cues. Young rats rubbed daily with cologne later showed a preference for animals also smelling of cologne. Methyl salicylate did not produce any alterations in social choice.

Other studies have dealt with the effects of early auditory stimulation. Henry (1967) showed that mice exposed between 12 and 20 days to a bell for 30 sec showed increased severity of audiogenic seizures later on. It is of interest that the strain used (C57BL/6) is considered to have normally a high threshold to sound-induced seizures. It is also worth noting that such a "priming" had effects whether the animals were awake at the

time or were anesthetized (ether or sodium pentobarbital).

A rather original experiment reported by Cross et al. (1967) involves more complex auditory experience. Rats were exposed early in life to the music of either Mozart or Schoenberg. Preference tests in adulthood (between different works of the same composers) yielded the surprising result that Mozart rats showed a definite preference for this music, but Schoenberg rats showed no preference. The authors attributed the latter effect to the high complexity of Schoenberg's music—one too high to be "an appropriate 'object' of attachment for the lowly rat."

Another study of more basic importance was carried out by Heion and Anchel (1964). They showed that rats exposed in early life to synchronous sensory bombardment manifested in adulthood EEG patterns that were altered toward being phased to this synchrony.

Procedures that involve manipulation of food intake have been used by a number of investigators. As early as 1941, Hunt (1941) found that feeding frustrations imposed on infant rats produced an increment in hoarding behavior later on. Likewise, Amsel and Penick (1962) using a similar manipulation involving degree of accessibility of food also found effects on later behavior. Rosen and Wejtko (1962) found that delaying weaning of rats until 42 days had no effects on emotional or eating behavior but did lower dominance in a competitive feeding situation. Novakova (1966) studied the relation between weaning age and acquisition rate and stability of a conditioned reflex (*drinking on a signal*). He found that rate of learning was inversely proportional to earliness of weaning, those weaned at 15 days showing the slowest acquisition rate, those weaned at 30 days the fastest rate. Similarly, stability of the trace was least in the early group and greatest in the late group.

As might be expected, neonatal X-irradiation affects later behavior (Meier et al., 1960; Agiawal et al., 1967) as does hyperoxia (Greenbaum and Gunberg, 1962). Meier and Garcia-Rodriguez (1966) have implicated, in the case of rhesus monkeys, mode of delivery (caesarian versus normal) as a factor that can alter emotional and avoidance learning ability.

Fig 10 Avoidance responding as affected by occipital cortex ablation at two age levels (Isaac and Baker, 1963)

Brain insult occurring early in life might be predicted to have severe effects, and Hebb (1942, 1949) has argued persuasively for this point of view. Indeed, it does seem to be true that clean surgical removal of large amounts of brain in the adult often exerts only small effects on psychometric intelligence. Support is given to these data by some of the animal work. Thus Isaac and Baker (1963) showed that bilateral and occipital cortex ablation produced large deficits in conditioned avoidance learning in relatively young animals (around 100 days) compared to older subjects (210 days). Surprisingly enough, the older subjects showed a facilitation of learning ability compared with controls. These data are shown in Fig 10. The reason for this is not clear. On the other hand, other work on animals, for example, the early studies of Kennard (1936) on monkeys and of Tsang (1937) on rats, have yielded opposite results. These investigators found that early operated subjects showed smaller deficits and any losses in function that were initially produced were recovered faster in these.

It is not entirely clear to what variables this apparent contradiction is due. It is possible, however, that rearing conditions have an important influence on the effects of brain injury and that the relatively rich environmental conditions to which most human adults have been exposed throughout their lives may serve to buffer biological intelligence against trauma. Most laboratory ani-

mals, on the other hand, do not have such an advantage, spending most of their lives in semirestriction. The validity of this notion is supported by the work of Schwartz (1964), who found that early brain lesions in rats (18 to 24 hours after birth) produced significant changes in Hebb-Williams maze performance only if the animals were reared in a restricted environment. Free-environmental rearing minimized the effects of ablation. These interesting results are presented in Fig 11. It should be noted, however, that the data of Isaac and Baker showing a *facilitating* effect of late lesions on performance can hardly be explained by reference to environmental variables. Possibly changes in arousal level were involved, these, in turn, affecting responsivity to the CS and UCS involved in the learning task.

A great deal of work has been carried out on the effects of early chemical manipulations. Deprivation of an essential dietary component such as protein will produce changes in learning ability at later testing (Penner, 1966). Likewise, adrenalin given preweaning can increase emotionality (Henderson and Eisner, 1966) and such substances as reserpine and deanol also produce changes in various behavioral dimensions including emotionality and discrimination learning (Meier and Huff, 1962). Meier and Huff argue, on the basis of their results, for a nonassocia-

Fig 11 Hebb-Williams maze performance as a function of neonatal cortical lesions and subsequent mode of rearing (Schwartz, 1964)

tionistic learning mechanism as the means by which the residues of early drug treatment are stored. In this connection, it is of interest to note that the magnitude of effects of early stimulation depends heavily on the chemical state of the animal. Young (1964) has shown that these were mitigated in rats if, prior to treatment, at 2 to 4 days, the animals were injected with either norepinephrine or chlorpromazine.

One of the more interesting lines of work in the present context, since it may bear on the well-known syndrome in human beings, has been on experimental phenylketonuria. Excessive overloading of phenylalanine plus tyrosine was imposed by Woolley and Van Der Hoeven (1964) on newborn mice. They reported maze deficits in adulthood as a result of this treatment and argued that a serotonic deficiency was directly implicated. On the other hand, as we noted earlier, Thompson and Kano (1965) did not find changes in intelligence as a result of maternal phenylalanine overload prenatally, though large changes in emotionality did appear. It is possible that the maze test of Woolley and Van Der Hoeven assessed emotional as much as intellectual differences and were the former taken out the latter might well not have appeared. Postweaning administration of the compound under discussion does appear to affect intelligence in rats (Louttit, 1962; Polidora et al., 1966), and monkeys (Waisman et al., 1959, 1960). However, it is still not certain whether these kinds of change are in any sense analogous to the very drastic effects found on phenylketonuria in human beings.

A final area of work has been concerned with early manipulation of sexual hormones and structures associated with sexuality. Levine and Mullins (1964) reported drastic changes in the vaginal cyclicity and mating behavior of female rats given 5 μ g to 100 μ g estrogen during the first few days after birth. These results were partially supported by Whalen and Nadler (1965). They found absence of ovulation in female rats treated with estradiol benzoate shortly after birth, and absence of lordosis, though some passive receptivity to males. Gray et al. (1965) reported that early injection in rats of either male or female sex hormone decreased emo-

tionality tested later in life. Sex and strain differences also showed up.

Environmental Enrichment and Restriction

Methods and Effects The technique of giving special practice to an animal in respect to certain functions or, conversely, restricting performance of those functions dates back to the late nineteenth century. In 1873 Spalding (see Spalding, 1954) showed that restriction of the incipient flight movements of young swallows impaired their flying ability later. A replication of this study much later by Dennis (1941) using buzzards yielded the same results. The effects of restriction of swimming in amblystoma was studied in a series of investigations started by Cairncross (1926). He found that paralysis of movement induced by immersion in chloroform produced no effects. Matthews and Detweiler (1926), however, were able to demonstrate that prolonged immersion in the solution beyond a certain period resulted in definite impairment. Restriction on the sensory side was used by Mettessell (1940) to explore the mode of song acquisition in roller canaries. Young birds which had never been allowed to hear the species song were still able to reproduce it properly. On the other hand, certain aspects of the song—vibration frequencies—could be altered by enforced exposure to an electronic oscillator. These observations have recently been extended by a number of workers (see Mailer and Hamilton, 1966) to song acquisition in the white-throated sparrow of the Bay area in northern California.

Work on the effects of *general* restriction and *general* enrichment was given its initial impetus by the theoretical stress laid by Hebb (1949) on the importance of early learning. We have already referred to his own study on the intelligence of home-reared compared with laboratory-reared rats. Several of his students and colleagues at McGill followed up these initial observations, notably Hymovitch (1952), Forgays and Forgays (1952), and Forgus (1954). They all were able to show quite clearly that the problem-solving ability of rats, as indicated chiefly on the Hebb-Williams maze test, was markedly raised by rearing in a so-called "rich" environment. This environment usually was defined loosely in terms of increased physical space and greater sensory complexity.

Another series of similar experiments was also started at McGill around 1950 on a higher species—the dog (Clarke et al, 1951). The general method was roughly similar to that used in the rat studies. Thus comparisons were made on a variety of tests between Scottish terriers that had been reared in relatively restricted laboratory cage situations with dogs raised as pets either in the lab or in homes in Montreal. The initial finding of Clarke et al showed that such manipulations produced dramatic differences in intelligence, emotionality, motivation, and social behavior. Follow-up studies were carried out over the next few years by Thompson, Heron, Melzack, and others (see Thompson and Melzack, 1956). Procedure was the same as that of Clarke et al with some additional control over degree of restriction. In a series of papers it was demonstrated that restriction produced greatly heightened diffuse activity level (Thompson and Heron, 1954a), marked deficiency in tests of problem solving, maze ability, and delayed responding (Thompson and Heron, 1954b), a tendency to epileptiform seizures (Thompson, Melzack, and Scott, 1956), and diminished social capacity (Melzack and Thompson, 1956). In addition, the restricted animals showed a curious apparent insensitivity to pain (Melzack and Scott, 1957). One experimental dog, for example, would continually approach and contact a lighted cigar or match without showing any obvious signs of distress but only general excitement. This qualitative finding was confirmed in a more controlled manner using an electrified, remote-controlled toy car. Some of the findings are shown in Table 2. The results were summarized by one of the experimenters as follows (Thompson, 1955, pp 130–131)

the restricted dogs present a picture of retarded psychologic development. In almost every way, then, behaviour is more like that of puppies than of mature dogs

The “puppylike” behavior that ensues on restriction is indeed striking and contrasts sharply with the more serious demeanor of normally raised animals. It is quite characteristic for most visitors to the laboratory to mistake the normal dogs for the deprived ones on account of the general ebull-

lence and alertness of the latter. It should be remarked, however, that a very severe restriction imposed on a few animals did produce an initial traumatic reaction at the time the subjects were first exposed to the world. This factor has been emphasized, as we shall see shortly, by other workers.

These findings have, in the main, been confirmed and extended by later investigators using other dog breeds (Melzack, 1962, Melzack and Burns, 1965, Fuller and Clark 1966a, 1966b, Fuller, 1966). However, interpretations of how the effects of restriction operate to produce the results they do have varied somewhat. This point we shall take up later.

The effects of restriction and enrichment on higher species were studied initially in more specific contexts. Thus the work of Riesen and his students (Riesen, 1958, 1961) has focused mainly on the specific perceptual handicaps that result from various types of visual deprivation. This work has shown clearly that exposure to light during early development is necessary for normal visual function. Later on chimpanzees reared in complete darkness show gross deficits, for example, lack of ability to fixate objects, impaired blink reflexes, poor depth perception, and poor size discrimination (Riesen, 1947).

Table 2 Effects of Early Restriction on Various Adult Behaviors in Dogs

Activity Levels (minimum activity in 4½ hour tests)		
Normal	14 11	
Restricted	21 32	
Intelligence		
	Delayed response (median delay reached in second)	Maze errors for 18 problems
Normal	240	237
Restricted	0	344
Social Behavior		
	Dominance (number of wins)	Social contact with another dog (seconds)
Normal	57	97 7
Restricted	7	64 5

From Thompson and Heron (1954a, 1954b), Melzack and Thompson (1956)

However, it was pointed out by Riesen (1951) that dark-rearing also produced physiological changes in the visual system—in particular, a marked pallor of the optic disk. This finding was confirmed by Brattgard (1952) using rabbits. Such a defect can be partly mitigated by rearing animals in such a way that they receive diffuse but not patterned light stimulation. Under these conditions, perceptual losses are again obtained though of considerably less severity. A daily ration of patterned light stimulation (1½ hours) was sufficient to allow almost normal development of visual function (Riesen et al., 1951). Later work has borne out and extended these general conclusions (see, e.g., Riesen et al., 1964).

The effects of specific restrictions have also been studied in lower species. Thus Spigelman and Bryden (1967) used rats to examine the effects of deprivation of one modality on performance that depended on the use of a different one. They found that animals peripherally blinded by enucleation shortly after birth did poorly compared to late-blinded animals on an auditory localization task. Curiously enough, the late-blinded performed better than sighted animals, although it is likely this difference was due to chance. Finally, early-blinded did better than late-blinded or sighted on a nonspatial auditory learning task.

Besides such specific deficits that ensue on restriction, other changes are produced. Especially since the work of Harlow (1958) on the development of affectional systems in primates, much attention has been given to the effects of different rearing procedures on social behavior. Starting in the late 1950s and 1960s, there has been a rapidly growing body of literature dealing with the general effects on primate behavior of partial or complete isolation. Three of the major centers for this work have been the University of Wisconsin, Cambridge University, and Yerkes Lab at Orange Park. At the first of these institutions, studies have been reported by Mason and Fitz-Gerald (1962), Rowland (1964), Mason and Sponholz (1963), and Griffin and Harlow (1966) among others. For the most part, early isolation produces striking deficits in social behavior and temperament. Animals so reared are socially inept and often very emotional as compared to normals. Learning

generally does not appear to be so greatly affected, though Griffin and Harlow (1966) have suggested that more complete testing procedures might well uncover deficits. The Cambridge studies have focused more on early social behaviors—particularly those occurring between adults and young and the effects of manipulation of these (e.g., by mother-infant separation) on behavior (e.g., Spencer-Booth et al., 1965; Hinde et al., 1966; Hinde and Spencer-Booth, 1967).

At Yerkes Lab, Menzel and colleagues (1963, 1964) compared normally laboratory-reared, restricted, and wild-born chimpanzees. He found that restriction produced timidity and lack of willingness to approach novel objects in their environments. Such differences in "responsiveness" appeared to be mainly a function of differences between rearing and testing environments. They tended to decline with age. These findings appear to be in essential agreement with those of the dog and monkey studies described previously.

Melzack (1965) has argued, somewhat in the same vein, that restricted dogs do not really have behavioral deficits and are on a continuum with normals in respect to psychological functioning. Restriction has the effect simply of increasing the novelty of cues in any testing situation confronted. Thus prior experience fails to make the positive contribution to performance that it does in the case of normals. In other words, restricted rearing produces a *different kind* of background but not necessarily abilities that are defective in any usual sense of this term. Melzack's point of view is backed up by data indicating that the EEGs of restricted dogs shift from predominantly low to high frequencies when they are permitted to look through their cage doors at a novel environment. Changes of comparable magnitude do not occur with normal animals (Melzack and Burns, 1965).

If early experiences of the kinds we are discussing affect behavior, they also must produce physiological effects. We noted earlier Schwartz' finding (1964) that the deleterious effects of very early brain damage in rats on later problem-solving ability can be attenuated by free-environmental rearing. In this study, cortical removal was carried out prior to environmental treatment. Thus it is reasonable to ask what would happen if the two treatments were reversed. Such a question

was posed in an experiment by Smith (1959), who compared the effects of extrastriate posterior or anterior cortical lesions in cage-reared as against free-environment reared rats. The results turned out to be rather complex. In the cage-reared animals, there appeared to be a positive relation between lesion size and loss in maze performance. This finding was considered to be in accord with Lashley's principle of mass action. In the "free" group, however, no such relationship appeared, for these subjects, locus appeared to be of importance—those with small posterior lesions performing worse than those with large anterior lesions. Such data are difficult to interpret, more especially since a later study (Witting, 1966) has reached the almost opposite conclusion that enriched early environmental experience may enhance cortical equipotentiality. The discrepancy between these two sets of results undoubtedly lies in the procedural differences involved and more exact specifications of which of these are the most critical should provide some interesting research possibilities.

Besides the possible influences early rearing experience may have on brain functioning, it has become very clear, in the last decade, that its effects can also extend to brain anatomy, physiology, and biochemistry. This has now been demonstrated quite decisively by the Berkeley studies of Kiech, Rosenzweig, and their colleagues. These investigators have shown using rats that (1) brain cholinesterase activity correlates positively with genetically based maze ability, (2) enriched environmental rearing results in significant increases in brain acetylcholinesterase activity in both the cortex and the rest of the brain, (3) enriched environmental rearing results in increased brain weight, mostly attributable to cortical thickness, and glia to neuron ratio increases. There is also a suggestion that those specific cortical areas that are subjected to greater input show greater anatomical change, (4) such effects can be obtained by manipulation of adult as well as of young animals, (5) an impoverished condition of rearing (i.e., confinement in a highly uniform and monotonous environment) will produce results opposite to those described above. This effect is due specifically to lack of stimulation rather than to any stressful aspects of the

situation (Rosenzweig, 1966, Krech et al., 1966).

This carefully done series of studies thus demonstrates clearly that early experiential variables can have profound influences on brain physiology and biochemistry. Which changes are the most crucial with respect to behavior still constitutes a problem. It is quite likely that the increase in acetylcholinesterase activity may indicate an increased number of functional synaptic connections and that this may be the dimension critical to improved intellectual functioning. However, this is a problem that still remains to be solved.

RNA (ribonucleic acid) has received a great deal of attention in connection with learning and memory functions. It is apparently also susceptible to early environmental manipulation, as shown in a study by DeBold et al. (1967). These investigators demonstrated with rats that rearing in dark from weaning for various periods of time and then being transferred to light produced alterations in the highest molecular weight fraction of RNA from occipital cortex. The Berkeley Laboratories have also implicated RNA in the effects of differential rearing procedures (Rosenzweig, 1966).

The apparent fact that the adult brain—at least in the case of the rat—is as responsive to environmental manipulation as the young brain is also worth noting, since it contradicts the common presumption concerning the greater plasticity of youth. Whether the same will also turn out to be true for higher species, however, remains to be seen.

The Essential Parameters The major question arising from the studies we have discussed concerns the specification of the variables mainly responsible for mediating the effects of restriction or enrichment—as well as the exact nature of the behavior changes they produce. One would expect at least that age would be implicated and this does in fact seem to be the case. Thus Hymovitch (1952), one of the few to employ an adult control group, found that late manipulation of environment produced no appreciable changes in the learning ability of rats. On the other hand, the same was not found by Woods (1959). His adult group did, in fact, show marked improvement in maze performance as a result of exposure to a free environ-

ment. Consequently, we must be a little cautious about drawing definite conclusions concerning the importance of age.

It should be noted also that age is a variable with two aspects. Thus some environmental experience may or may not have an effect, not only because of the particular developmental status an animal has but also because of the experience the animal has had up to that point. These are two separate problems, but they are hard to disentangle.

It is clear also that the independent variables are very complex. The categories "enriched" and "restricted" are global ones involving many factors. The former usually is defined operationally in terms of larger amounts of space, more complex sensory (especially visual) stimulation, and the provision for more complex modes of motor response. The latter category, of course, involves presumably the opposite features. What is not yet fully understood is which of such dimensions is mainly operative in producing changes in behavior, and also whether the same variable is involved in effects of both enrichment and restriction.

Hymovitch (1952) was one of the first workers to focus on this problem. In his free-environment situation, he had some subjects which were allowed to roam freely about the full extent of the cage, while others were confined in small wire-mesh cages in the enclosure. The confined subjects had extra visual stimulation but no opportunity to respond very much to it. Results showed that the two experiences had equivalent effects on problem-solving ability. Consequently, Hymovitch concluded that perceptual experience was the critical factor in early emotional experience. On the other hand, two experimenters from the McGill laboratory, Forgays and Forgays (1952), made a similar comparison and found the very opposite to hold true. Thus rats allowed motor activity in addition to broad perceptual experience showed better performance than subjects provided only with the latter. What probably is critical is the similarity between the so-called rearing environment and the later testing situation. This point was demonstrated by the Forgays, who reasoned that the free-environment situation involved continued opportunity to fixate on distant visual cues, whereas restriction necessarily forced animals to attend to proximal

stimuli. If this were true, then changing the position of the maze in reference to the room after a certain level of performance had been achieved should produce a greater disturbance for free-environment than for restricted animals. This, in fact, turned out to be the case.

The series of studies carried out by Foigus (1954, 1955a, 1955b, 1958) has made essentially the same point. That is to say, the findings seem to indicate that the effects of rich or impoverished rearing are "good" or "bad" relative to the demands of a criterion task. Theoretically, this means that provided the appropriate test could be supplied, restriction might turn out to have good effects and free-environment rearing to produce deficits in performance. Perhaps the most sensible position to take is to define as a rich environment one that will facilitate performance on a maximum number of task dimensions. This has been generally the position taken by Meier and McGee (1959), who suggested that an enriched early environment furnishes opportunity for progressive stimulus differentiation in all modalities including the kinesthetic. The more modalities that are involved, the richer the experience can be considered to be and the more performance in a variety of tasks should be facilitated.

We may still ask, however, whether such a passive exposure to a complex environment and the perceptual differentiation this produces is the only variable at work. It can be argued that active exploration of the world and the setting up of certain sensorimotor coordinations will also be of great importance. This notion has been put forward especially by Held and his colleagues, who have stressed the importance of the motor side in sensorimotor development—particularly the place of reafferent stimulation that ensues on muscle action. In a series of experiments using human and animal subjects, these workers have manipulated this variable by comparing the results of discrimination training under conditions of self-produced or active movement with those under conditions of passive or experiment-produced movement (Held and Heim, 1963, Held and Schlank, 1959, Held and Bossom, 1961). In one of these experiments, for example, an ingenious carousel arrangement was used. This allowed one member of a pair of subjects to explore actively

the surrounding environment but the other, yoked to the first and restrained in a box, had only passive exposure to the same environment. Subsequent testing indicated that the "passive" kittens compared to the "active" animals were deficient on tests of visually guided paw placement, discrimination on a visual cliff, and development of a blink response (Held and Heim, 1963). The general conclusion is that both for the normal development and maintenance of visual spatial performance, the patterns of reafferent stimulation arising from active or self-induced movement are essential. Although their experimental procedures involve difficulties that make precise control over the relevant variable rather imprecise, these do not greatly detract from the validity of this idea.

If the advantages of enriched environmental rearing lie in the maximizing of compatibility between general living circumstances and test conditions, we might expect that the noncompatibility that ensues on severe restriction will have at least two effects. The one we have emphasized so far has been of a cognitive sort in that it relates to the adequacy of intellectual preparation that a subject, because of prior rearing conditions, can bring to some criterion task. However, there is an affective factor also involved. A sharp disparity between what an animal has become used to over a long period of time and what is suddenly imposed on him is likely to produce serious emotional disturbance, and this in turn may cause a deficit in performance. The importance of such a factor has been particularly stressed by Fuller and Clark (1966a, 1966b), who have referred to it as the "postisolation" syndrome. In one experiment they were able to show that the trauma of emergence could be reduced by means of a tranquilizer—chloropromazine—and this resulted in a smaller deficit in performance. Similarly, in a second study they found that approach and contactual behavior to objects and other dogs following a period of isolation could be aided by supplying some pre-test familiarization with the testing space.

In the opinion of the writers, it is quite likely that postisolation depression is of importance. But it perhaps should not be regarded as an exclusive alternative to the factor of perceptual-motor experience, nor, indeed, is it probably as critical as the latter

In the McGill studies both with dogs and rats, pretraining procedures prior to many of the tests used guaranteed that emotionality was a very minor factor in determining scores. And it seems improbable that the emotional trauma of being taken out of isolation could be long enough or intense enough to produce by itself large and inevitable losses in intelligence and other functions. Nonetheless, Fuller and Clark have done a useful service in drawing the attention of researchers to the postisolation syndrome. It is certainly an effect that must be reckoned with in any early isolation study.

Early Social Influences

One of the most important types of early environmental influence relates to the social interactions that occur between a young organism and its parents, peers, or others close to it physically. In psychology, Freud was one of the first to suggest that the patterns that were set up in early childhood could become prototypic of all later social behavior and attitudes. His specific formulations were couched in rather overdramatic and literary terms but there is no gainsaying the validity of the general point. In biology, Charles Darwin came to regard emotional expression and its role in animal communication as having a prominent role in determining the course of evolutionary change. Subsequently, a great many workers in the biological area, particularly those concerned with ecology, have concerned themselves with trying to specify the dimensions of social behavior that contribute to population parameters and the dependence of these on genotype and environment.

In the present context, however, this orientation is of less relevance. What we wish to discuss here relates not so much to group characteristics, but rather to the nature of social interactions between individuals and how these are influenced by the encounters one animal has with another early in life. Since the volume of work done is enormous, we shall consider only three particular lines of work as reasonably representative of this focus: (1) the work on imprinting, especially in avian species, (2) socialization processes in the dog, and (3) affectional systems in primates. We shall review briefly each of these areas and also discuss some selected studies that seem to be of importance.

Imprinting The extensive work in this area has been reviewed by Sluckin (1964) and by Bateson (1966). It has been known since the nineteenth century and probably well before that very shortly after hatch, young birds will respond positively to different objects in the environment and as a result may show to these strong and relatively permanent attachment behavior. The person most responsible for putting into a formal theoretical context what had previously been simply an interesting bit of natural history was Konrad Lorenz (1935). He emphasized the following aspects of imprinting: (1) the critical period during which it can occur, (2) its irreversibility, (3) its species characteristics in respect to the kinds of stimuli and response patterns it involves. Much of the work done on the subject has been directed toward exploring one or other of these problems. What has become more and more clear is that the phenomenon is a general one that probably takes in a great diversity of apparently distinct types of early learnings, including, for example, attachment to territories and food objects (Hess, 1964; Bateson, 1966). In addition, it seems likely that taken broadly it also occurs in species other than precocial birds, for example, some mammals such as goats and sheep (Scott, 1945; Smith et al., 1966; Cairns and Johnson, 1966; Cairns, 1966a), perhaps some of the canidae (Scott and Fuller, 1965), and possibly primates (Sackett et al., 1965).

From the standpoint of the early experience framework, the important feature of the phenomenon of imprinting lies in the fact that it represents a case of long-term social attachment set up during a short (and perhaps critical) period during development. In lower animals at least, such an attachment is usually defined in terms of a stronger following response to the surrogate as against weaker following of a neutral object, or a simple preference of the former over the latter (Bateson, 1966).

Besides these, other measures can be used to indicate attachment. For example, avoidance of unfamiliar objects is stronger in birds imprinted on a particular surrogate (Jaynes, 1956; Gupton, 1959), likewise, distress calling often occurs in the temporary absence of the imprinted object and the general resistance of the animal to stress seems to be

greater (Thompson and O'Kieffe, 1962). It has been shown that the surrogate can quite readily function as a reinforcing stimulus in a maze-learning (Campbell and Pickleman, 1961) or bar-pressing situations (Peterson, 1960; Hoffman et al., 1966a, 1966b). Finally, there is limited evidence that imprinting influences mate-choice in the direction of choosing animals like the imprinted object, as well as promoting flocking and general social behavior later in life, although the conditions under which this occurs may be rather particularized (Bateson, 1966). When such a relationship does obtain, it is possible that it may have important evolutionary consequences, and some workers (e.g., Mainardi et al., 1965) have constructed models relating polymorphism and eventual speciation to mate-preferences arising from early imprinting. Data relevant to this hypothetical relation have been gathered by Cooke (unpublished manuscript, 1968) on the blue goose and the snow goose.

As indicated previously, the precocity and rapid development of the species usually involved in imprinting studies have tended to give to the phenomenon a quality of special mystery and drama that may make it seem to have a narrower application than it really does. For whatever reasons, most young animals probably become attached to and prefer those social objects to which they are first exposed, and indeed it does not strain credibility to suppose, as both Gray (1958) and Bowlby (1958) have suggested, that this applies as much in the case of children as in birds and lower species. Certainly, the consequences of making and breaking of early social attachments have been explicitly the concern of much of classical psychoanalytic theory and its more modern offshoots. This point will be taken up again in the section dealing with studies on children.

We may next ask what happens when social attachment or imprinting does not have the opportunity to occur early in life? Some of the more important work in this problem has been carried out with dogs and monkeys. Let us now consider a sample of these researches.

Social Isolation in Dogs During the late 1940s, a program of work was set up at the Jackson Laboratory, Bar Harbor, Maine, to study the genetics and social behavior of the dog. A book of this title summarizing almost

20 years of work has been published (Scott and Fuller, 1965). One of the most interesting lines of research carried out was concerned with the socialization process. Several studies may be cited here as representative.

The first (Elliot and Scott, 1961) concerned itself with the immediate effects on puppies of isolation from the mother. Dependent variables measured were activity level and amount of vocalization. Besides isolation itself, a major independent variable was age. Results are summarized in Fig. 12. They show quite clearly that, in terms of the behavioral indices used, emotional upset is maximal around 6 to 8 weeks of age. This presumably indicates that social attachment to the mother is strongest around this age in the puppy. Hence Scott (1962) and Scott and Fuller (1965) have referred to the time between about 4 to 14 weeks as the *socialization period*. It is also true, however, that it seems to be a time when affective relations with any part of the environment—animate or inanimate—may be formed and when a puppy is likely to show the greatest emotional response to any unusual or disturbing stimulus (Fox and Stelzner, 1966). Consequently, we should perhaps be careful not to categorize it in too narrow terms.

If it is true that the formation of social attachments is one of the more important processes going on in the 4 to 14-week-old puppy, we might then guess that isolation during this time would have drastic effects on later social behavior. This indeed seems to be true. Pfaffenberger and Scott (1959) studied the reasons for failure in animals being trained as guide-dogs for the blind. One of the most critical factors turned out to be a protracted period during early life involving minimal human contact. For accidental reasons, some dogs were kept in the school for some weeks beyond the end of the socialization period (i.e., around 12 to 14 weeks) before being farmed out to homes. These animals tended to perform poorly in the criterion tests. Similarly, Freedman, King, and Elliot (1961) found that the extent to which a dog would make social contact with another dog or with a human being was directly proportional to the amount of social contact it had been permitted with them between 4 and 14 weeks. According to the authors, animals isolated between these ages were never able to

Fig. 12 (a) Vocalization in puppies as a function of familiarity or nonfamiliarity of environment and age (b) Activity scores at different ages as a function of the same two variables. In both cases, note peaking at 6 to 10 weeks (Modified from Elliot and Scott, 1961.)

develop the ability to socialize normally. The dimensions of contact have also been examined. Stanley and Elliot (1962) explored

the effects of variations in type of social contact given to a group of basenji puppies beginning at 6½ weeks of age. Contact with a passive person apparently has as large effects on later behavior as receiving active handling.

Isolation in adulthood does not have the same effects. At least if it is imposed for relatively brief periods, it will certainly act as a stressor (Scott, 1950), but will probably not result in an antisocial or asocial animal. However, the effects of drastic long-term restriction in adults of higher mammals have not been fully explored.

The major point emerging from the dog studies is that the opportunity to have social contacts between 4 and 14 weeks is very important to the development of a mature animal. This conclusion agrees with those obtained by Melzack and Thompson (1956), to which we have already referred. These investigators imposed severe restrictions on dogs for the first 10 months of life. One of the dimensions affected by this treatment was social behavior. The Bai Harbor studies, however, go a long way to delimiting the age range of specific conditions that are relevant to social behavior in particular.

Affectional Systems in Monkeys In the late 1950s, H. F. Harlow at the Wisconsin Primate Laboratory initiated a series of studies in a curiously neglected topic in psychology—the nature of love. He has defined five so-called affectional systems: (1) the infant-mother system, (2) the infant-infant system, (3) the heterosexual or adult male-female system, (4) the maternal or mother-infant system, (5) the paternal or father-infant system (Harlow et al., 1963). All of these appear to be affected by early social restriction such as is involved especially in surrogate-rearing. For example, females which have been raised in this manner turn out to be exceedingly difficult to breed even with the most experienced males (Harlow, 1965), and those that are bred and produce young make exceptionally poor mothers. Harlow et al. (1963, pp. 275–276) write of the behavior of unmothered mothers as follows:

All five females were totally hopeless mothers, and none of the infants would have survived without artificial feeding in the first days or weeks of life. Two mothers were essentially indifferent to their infants, three

were violently abusive. Indeed, the last infant was separated when it became apparent that otherwise it would not live. The maternal inadequacies of these animals cannot be attributed to faulty responding by the babies. Early in life the babies repeatedly offered visual and auditory cues normally appropriate for creating maternal responses, and as far as the first four infants were physically able to initiate approach and body-contact responses, they made repeated attempts to attach to the mothers, only to be repulsed and rejected. So strong were these contact-seeking responses in two infants that they withstood brutal and continuous abuse by the mothers until they attained the breast for reasonable periods of time.

Temporary separations of short duration can also have effects on behavior and these appear to be similar to those found in human children. Jensen and Tolman (1962), Seay et al. (1962), and Seay and Harlow (1965) used various lengths and degrees of separation. They demonstrated increases, on the part of the infants, in "crying," self-directed mouthing, depression, and general lethargy. Hinde et al. (1966) and Kaufman and Rosenblum (1968) have verified and supplemented these main results. The latter two authors have usefully summarized the primate work on the problem and pointed up the similarities between such observations with monkeys and those with children. It is of interest to note, in this connection, that rearing monkeys with humans produces animals that prefer the company of human beings to other monkeys when given a choice at 2 to 3 years of age. Animals reared in isolation or with both humans and monkeys turn out to prefer monkeys (Sackett et al., 1965).

It is still uncertain how long or how severe social isolation must be to produce effects. Three months of social deprivation produces initially "severe depression" and heightened "self-directed" activities but apparently does not greatly affect social responses (Giffin and Harlow, 1966). On the other hand, social potentialities are effectively destroyed if isolation lasts as long as 6 to 12 months after birth (Harlow, 1965). As a result of such a prolonged period of social restriction, a monkey appears to become almost totally autistic and incapable of orienting appropriately to an-

other animal whatever its sex or age. It is difficult to know exactly what are the most critical aspects of the isolation experience that produce such results. At least in the case of monkeys, physical contact between animals must be an important dimension. It does appear to be true that social and sensory deprivation tends to reduce the extent to which contacting behavior is initiated. That is to say, isolation produces monkeys that dislike touching another monkey. Since social behavior in this species involves a very heavy component of physical contact, it is therefore markedly distorted (Sackett, 1967).

The manner in which such a variable operates in other species is not known. It seems likely it is most important in the case of human beings. However, as with general environmental restriction, more work will be needed to locate the variables most critically implicated. For the time being, however, we must be content with the well-documented empirical evidence that social behavior in all its various forms, and in a variety of species, depends on the social attachments that are set up early in life.

HUMAN STUDIES

We have broken down our review of postnatal early experience studies in human beings according to a division similar to that used in our discussion of the animal work. However, as we have already indicated in our brief review of methods, the relevant experiential variables in humans tend to be rather broad ones that do not easily lend themselves to neat categorization. Thus "institutionalization" or "nursery school attendance" must incorporate many of the kinds of influence that we have been able to consider separately when dealing with the animal work. As a result, the recurrence of these variables across sections may give the appearance of redundancy. This is unfortunate but seems to be preferable to collapsing distinctions which the work done with animals suggests are of great importance.

General Massive Stimulation

Institutionalization and Stimulation. Children living in institutions have had an unbelievably high mortality rate, which has decreased only recently. Of 10,272 children

admitted to the Dublin foundling home between 1775 and 1800, 45 survived (Kessen, 1965). At the beginning of this century one of the major foundling homes in Germany had a mortality rate of 71.5% in infants during their first year of life (Spitz, 1945). By the 1930s the situation had improved sufficiently that the death rate among institutionalized children compared favorably with that of noninstitutionalized children. At this time, however, a new problem came into focus. Investigators began to report that among children reared in an institutional setting the incidence of psychological disturbance was alarmingly high (Duffee and Wolf, 1933, Lowrey, 1940, Bender and Yarnell, 1941, Bakwin, 1949). Two factors were generally deemed responsible for the observed psychological abnormalities—lack of stimulation and absence of the mother.

The first large-scale study of institution infants less than 1 year old was undertaken by Spitz (1945). He compared the development in the first year of life of infants raised in two different kinds of institutions. The one, *Nursery*, was for the children of delinquent girls who were in a penal institution; the other, *Foundling Home*, was for children whose mothers could not support them. In *Nursery* the occupants were provided with toys, could see all that was going on around them from their cribs, and were fed, nursed, and cared for by their own mothers or by full-time mother substitutes. Children in *Foundling Home*, on the other hand, had few toys and could see little of the world around them because sheets were regularly hung over the foot and side railings of their cots. They interacted with other people only at feeding time, when busy nurses came to look after their needs. They lay supine in their cots for so many months that hollows were worn into their mattresses and, by the time they were physically able to turn themselves in their cots (about 7 months of age), these hollows prevented them from doing so. Thus, at the age of 10 or 12 months, they were observed lying only on their backs and playing with the only toys they had—their hands and feet.

When he compared the Developmental Quotient scores (Hetzler and Wolf, 1928) of the two sets of infants, Spitz found a large difference. There was a dramatic reduction in score between the first and last third of the

first year of life for Foundling Home infants. On the other hand, the comparable scores of Nursery infants and of two control groups of noninstitutionalized infants remained approximately the same. Foundling Home children also showed a marked reduction over the year in "Body Mastery" scores as compared to scores of Nursery children. Apart from severe developmental retardation, Spitz also noted unusual reactions to strangers by Foundling Home children in the last third of their first year of life, ranging from extreme friendliness to blood-curdling screams. In addition, they were extremely susceptible to infection and illness of any kind, despite what Spitz reports as impeccable hygiene and precautions against infection in the home. During Spitz' stay an epidemic of measles struck the institution, leaving a staggering number of the children dead.

A follow-up two years later (Spitz, 1946) revealed continuing large developmental differences between Foundling Home and Nursery children. Although conditions in Foundling home had been greatly improved—the children had been moved into a large, sunny room where they interacted with each other and with nurses who were constantly in attendance—the 21 whom Spitz was able to study were retarded in physical development, toilet training, speech, and ability to feed and dress themselves. Thus the unfortunate conditions under which they had lived for their first year of life seemed to have had irreversible effects on their subsequent development. The children in Nursery generally left the institution when they were 1 year old, but Spitz was able to observe a few who were there between 13 and 18 months of age. Their development was quite adequate and, in fact, in most cases the Developmental Quotient surpassed the normal age level. During the 3½ years in which Spitz had contact with Nursery not a single child died.

The effects of institutionalization which Spitz found in Foundling Home children could well be attributed to a lack of general environmental stimulation. Spitz chose, however, to maintain that the children suffered because their perceptual world was lacking in human contact—that of either a mother or a mother-substitute. He argued that "perception is a function of libidinal cathexis and therefore the result of the intervention of an emo-

tion of one kind or another" (1945, p. 67), and it is only through the intervention of a mother that emotions are provided for a child. The children in the Nursery experienced an adequate mother-child relationship. It was, in fact, an exaggerated one. Since many of the opportunities these mothers might have had for social contact were obviously denied them in the penal setting, they focused even more of their emotional attachments on their babies. They were in constant competition with other Nursery mothers as to who had the best baby and were intensely jealous of any attention others gave to their infant. It may be that this intensified care given to Nursery children produced the accelerated development which Spitz noted in his follow-up.

Spitz was not alone in attributing the detrimental effects of institutionalization to maternal deprivation. As we have indicated earlier, Ribble (1944) maintained that the newborn child urgently needs a long and constant period of psychological mothering, by its own mother or a single mother substitute, to counteract biological anxiety and maintain body integration while the nervous system is maturing. Babies deprived of mothering, she reported, develop marasmus, a condition of physical debilitation. Marasmic children also display a form of either negativistic excitement or regressive quiescence. When given care and massage by a "foster mother" these children show a remarkable recovery, with restored appetite, alertness, and reflex excitability.

The severe retardation of infants in institutions is still being documented (Provence and Lipton, 1962). In studying the occupants of a nursery where there was minimal contact between caretakers and children and lack of individualized care these investigators noted substantial impairment in social responsiveness, language development, body awareness, and pain avoidance. They found a large discrepancy between maturation of the motor apparatus and its use by the infant, a difficulty in modulating motor impulses to produce smooth movements, and a diminished impulse to reach out toward people and objects. Again, they attribute much of this retardation to lack of continuous care by a mother figure.

Goldfarb (1945a, 1945b, 1947, 1949) compared the development of children who had

lived in an institution up to the age of 3, at which time they had been placed in a foster home, with that of children who had been placed in a foster home before age 1. All the children had been separated from their mothers before they were 9 months old. The 30 children whom Goldfarb studied most intensively ranged in age from 10 to 14 years, and all were living with foster parents at the time of his investigation. The institution in which half of these children had lived for the first 3 years of their lives was very similar to Spitz' Foundling Home. Although it was immaculate in physical hygiene, it involved for the children almost complete social and sensory isolation during the first year of their lives. They were cared for by a number of staff members with frequent personnel changes both during the course of a day and over a period of months. Thus they lacked any opportunity for intense and continuous contact with a specific adult. Conditions in the institution during the next 2 years of these children's lives were only slightly better. These children, as compared with the 15 who had had immediate placement in a foster home after separation from their mothers, were deficient in intelligence, ability to conceptualize, and speech development. They were also restless, less able to concentrate, and poorer in school achievement. They were unpopular, socially immature, aggressive, and insatiable for affection, although unable to form any genuine attachment. An inability to adhere to rules or to display any sign of guilt after deviation completed a picture remarkably like that painted by Bender (1947) in her description of the so-called "psychopathic behavior disorder in childhood." These emotional and intellectual consequences were blamed by Goldfarb on the lack of mothering during the first three years of life. In spite of the fact that the foster homes to which both groups of children had been assigned were equivalent in the environments they provided, the differences existed. Goldfarb thus concluded that the early effects of institutionalization were irreversible.

Retrospective studies of adopted children continue to suggest that maternal separation early in life may have lasting negative effects. It appears that a greater proportion of adopted children are being treated for emotional disturbance than one would expect

from their incidence in the general population (Bostock, 1961). Those with emotional problems display impulsivity, hostility, delinquency, and other aggressive symptoms. Menlove (1965) found the incidence of hyperactivity, hostility, and negativism to be greater among a group of adopted than non-adopted children.

In a report prepared on behalf of the World Health Organization, Bowlby (1952), citing an extensive list of studies including his own (Bowlby, 1940, 1944), concluded that when a child is deprived of maternal care his physical, intellectual, and social development is almost always retarded. In addition, Bowlby indicated that the effects of early deprivation are permanent. "This is a sombre conclusion which must now be regarded as established" (p. 15). It appeared to Bowlby that maternal deprivation before the age of 6 months was less detrimental than that occurring later. But lack of opportunity during the first 3 years of life for the formation of attachment to a mother-figure, deprivation of a mother-figure for a limited period of time, or changes from one mother-figure to another during the same period of time were all experiences, he felt, which would produce the affectionless and psychopathic character so many investigators had described. Beyond the age of 3, Bowlby suggested, a child becomes more able to tolerate maternal absence for a few days or weeks at a time, and, by age 7 or 8, of a year or more.

Criticism of the Early Studies In spite of the large volume of work pointing to the negative consequences of a lack of early mothering, the findings and conclusions have not gone unchallenged. The methodological adequacy of many of the studies has been questioned, studies which suggest that not all children are adversely affected by institutionalization have been reported, and interpretations of the data have been made. We shall deal with each of these in turn.

Methodological Criticisms The work of Ribble and Spitz has come under extensive fire by Pinneau (1950, 1955). In a 1950 *Child Development* article Pinneau criticized Ribble for her assumptions that in infancy there is a tendency to functional disorganization and that psychological mothering is needed for normal development. The evidence shows, Pinneau claimed, that the nor-

mal infant circulatory system is fully adequate to meet the demands placed on it, that handling is not necessary for the majority of babies to help them breathe properly, and that the sensitivity of the infant's digestive system is not due to a lack of mothering. In concluding that marasmus is not due to lack of mothering Pinneau regretted, along with others (e.g., Orlansky, 1949), that Ribble had not drawn a line between her empirical findings and her personal opinions. At the same time, though it may be true that data on the physiological make-up of infant systems does not completely favor Ribble's position, it does not favor Pinneau's either (see Wolstenholme and O'Connor, 1961).

Pinneau's criticism of Spitz (Pinneau, 1955) included criticism of Spitz' failure to state whether or not there were congenital abnormalities in Foundling Home children which might have accounted for their developmental retardation. Spitz also failed to pay attention to possible differences between the mothers of the two groups of children which might, at least partially, have caused the differences in the children. These included factors such as the mothers' intellectual and socioeconomic backgrounds and conditions of health. In addition, Pinneau pointed to the questionable validity of the Hetzer-Wolf baby tests which Spitz had employed and to their lack of predictive ability for later performance.

Spitz lost many of the children in his sample through outplacement. It seems evident that these would be the more desirable ones, and that hence only the less well-developed children would be left behind for him to study. Again, one wonders if the high mortality rate among foundling home children was due to maternal deprivation or, rather, if it was because these infants were more susceptible, because of their inactivity, to such problems as respiratory infection.

Children who are committed to institutions do not constitute a random sample from the general population. For that reason the results of institutionalization studies cannot be generalized to the general population. It seems possible that a high proportion of mothers who give up their children to institutions are likely to be from a lower socioeconomic class, unwed or deserted by their husbands. We might then expect their offspring to have a

poorer genetic background than that of children reared in a home. If a mother gives up her child the chances seem great that her pregnancy was unwanted and that she was anxious and tense during it. It is also likely that she may have received less adequate medical attention during pregnancy than do mothers of wanted children and that she may have had a more difficult birth with resultant damage to her child. All these factors, as we have noted in a previous section, may produce serious—although undiagnosed—psychological and physical disturbances in the child before he is ever placed in an institution. Brain-damaged children suffer more from isolation than do normal children (Bender, 1950). Hence we would expect a quite different reaction to the social and sensory isolation of an institution from damaged children, who may constitute a large percentage of its population, than from normal children.

Goldfarb's studies have also come under critical attack (e.g., O'Connor, 1956; Casler, 1961). Perhaps the most important criticism is that his two groups of children may well not have been matched for every variable except the incidence of institutionalization. Goldfarb is careful to show that the foster homes in which his children had spent the greater part of their lives were identical and that, in fact, the true mothers of the *institution* children were superior to those of the noninstitution ones. Unanswered, however, is the question of why 15 of the children had spent the first 3 years of their lives in an institution. Was there something wrong with them that they had not been placed in foster homes soon after separation from their mothers? How did they differ from the children who did go almost immediately into foster homes, and what made them less desirable for this kind of placement?

Contradictory Data Not every observer found the overwhelmingly negative effects of institutionalization described by Bowlby in his WHO report. Nor were others so pessimistic about the eventual fate of children who were raised in foundling homes. In a follow-up study of 60 children who had been admitted to a tuberculosis sanitarium before they were 4 years old, Bowlby, Ainsworth, Boston, and Rosenbluth (1956) were forced to conclude that the case against maternal deprivation had been overstated. These chil-

dren, aged 6 to 14 years at the time of the study, had spent varying amounts of time in the sanitarium, ranging from a few months to over 2 years. Compared to a matched control group of school classmates they did not show any reduction in intellectual functioning. It was true that, according to the examiner's judgment, fewer of the institutionalized than the control children could respond well in the test situation and, according to teachers, they displayed more withdrawal and apathy, rough behavior and temper. On the other hand, few of the sanitarium children were delinquent and over half of them were capable of establishing good social relationships with their peers. Thus Bowlby et al. stated that the belief which they had had to that point, that institutionalization and privation commonly lead to the development of psychopathy and affectionless characters, was incorrect.

In a study of six orphaned children who had spent most of their lives in a concentration camp, Freud and Dann (1951) found that, at the age of 3, these children were not delinquent, deficient, nor psychotic, nor was their ability to form emotional relationships and attachments, at least for each other, impaired. Similarly, Freud and Burlingham (1944) noted that children in their nursery often developed better than in the average household. Rheingold (1956) found that the average intellectual level of institution infants she studied was within normal limits on the Cattell scale, a report in striking contrast to those noting a severe reduction in intellectual functioning among orphanage children. In a later study Rheingold and Bailey (1959) report that these same children were friendly, intelligent, and in no way emotionally or mentally retarded. And, finally, in a study of another group of "deprived" infants, Rheingold (1961) states that they were as interested and competent as home-reared control infants and even more positively responsive to the examiner than the control children.

In a study of children raised in a foundling home ("the Crèche") in Beirut, Dennis and Najarian (1957) did find these children exhibited some intellectual retardation but found no evidence that this retardation was irreversible. A ratio of one attendant to ten children meant that children in the Crèche received little more than the essentials of physical care. They were not held while they were

being fed, but, instead, were given a bottle propped on a small pillow from which they drank as they lay on their backs. The infants were swaddled—a Near Eastern practice—until they were 4 months old so that their opportunity for activity in arms and legs was severely restricted. The cribs in which they lived were covered around the sides, as in Spitz' Foundling Home. Compared to children raised in homes in Beirut these babies, after 3 months of age, were significantly lower in intelligence as measured by a modified Cattell infant scale. However, children in the same institution who were between 4½ and 6 years of age were not retarded in their performance on the Goodenough draw-a-man test, the Knox cube test, or the Poiteus mazes when compared to American norms. Since the older children had received the same kind of care as the infants Dennis and Najarian measured, and the home's admission requirements had not changed, we can only assume that whatever experiences the infants had missed in infancy were made up at a later date. Hence, at least the effects of institutionalization on intellectual development appear reversible. Moreover, since Crèche infants had never had their mothers with them, the retardation which Dennis and Najarian observed could not have been due to a break with the mother. Spitz' suggestion that this was the reason his Foundling Home infants were retarded is therefore questionable.

The fact that a number of investigators have not discovered negative effects in *all* children raised in institutions, *in spite of the fact that they had all suffered maternal deprivation*, means that other explanations for these effects, where they occur, must be sought. A likely explanation lies in the suggestion that children in institutions suffer from perceptual deprivation and restriction of learning opportunities.

Alternative Explanations Dennis and Najarian suggest that Crèche infants performed as poorly as they did on the Cattell infant scale because they had been deprived of normal opportunities for learning, which most children reared in family homes have had. Items measuring intellectual development between the ages of 3 and 12 months require an infant to sit on an adult lap, and this was a luxury to which Crèche infants were unaccustomed. They were unable to hold their

heads erect and steady and had had no opportunity to practice manual skills directed by vision, which are necessary for performance on the Cattell test. Once given the opportunities for learning which they had missed, these children should have performed as well as any noninstitutionalized infants and, indeed, by the age of 5 or so they appeared to do just this.

Clearly, an environment lacking variety in material surroundings, and in which there is minimal opportunity for interaction with caretakers, is going to be deficient in learning opportunities. We would expect its inhabitants to be retarded intellectually, in motor and language development, and in many social skills. These deficits we shall discuss later when we deal with the effect of qualitative alterations in an organism's environment. The data previously presented, however, on the effects of general, massive stimulation on animal development do suggest that much retardation in orphanage children is due to a lack of general stimulation. The variables of handling, shocking, stress, and so forth, which have been discussed sound very much like the "stimulus feeding." Ribble suggests mothers provide when they stroke, hold, rock, and move in front of their infants. Mothers, in the course of daily care of their children, provide a great deal of stimulus feeding. But much of the kinesthetic and tactile stimulation to which home-reared children are exposed continuously may be denied to institution children, who spend so much time unhandled and lying in their cribs. Home-reared children are not generally left alone in cribs draped with sheets. They are given extensive auditory and visual stimulation in the course of being exposed to the activity going on around them. That the opportunities for this stimulation are generally mediated by a mother figure, however, does not mean that her absence will be detrimental to all forms of development. Provided that a child receives this perceptual stimulation, be it from a number of different caretakers or through inanimate means, he should suffer less than a child totally deprived.

The function of perceptual stimulation and the mechanisms through which it influences development have already been noted. Clearly, all that has been suggested in reference to the animal studies is relevant to the

human data as well. In brief, one of the important functions of general stimulation may be to produce habituation in the young organism, that is, a tendency to be less aroused or more easily aroused by stimulus change. A child deprived of adequate amounts of stimulation may never show normal general reactivity to his environment. His general responsiveness to any alteration in stimulus conditions may be no different from what it would have been had there been no exposure to early stimulation. Thus he might be characterized by the adjectives nervous, phlegmatic, jumpy, emotional, docile—adjectives which might easily be applied to children in institutions. In addition, if children are not habituated to stimuli which elicit startle, defense, and emotional behavior, it is quite probable that their early learning experiences will be interfered with by these competing unlearned emotional behaviors.

It has been suggested (e.g., Thompson, 1958, 1960, Casler, 1961) that the ill effects that have been attributed to maternal deprivation during the first 6 months of life are, in fact, due to perceptual deprivation while those occurring after 6 months are due to perceptual deprivation and the affective components that accompany the breaking of an established emotional bond between mother and child. (We should also add to this the ill effects of never having formed an emotional attachment to a mother figure.) The cutoff age of 6 months is by no means an arbitrary one. Bowlby (1958) notes that children who are separated from their mothers after this age fret, but those that are separated before do not. Spitz (1946) has suggested that it is not until the age of 6 months that the average infant is able to discriminate between his mother and other human beings. Thus we would not expect him to be upset before that time at any attempt to replace her. In a study of 76 babies admitted to hospital, and thereby separated from their mothers, Schaffer and Callender (1959) found that those 6 months of age or less did not protest and readily accepted mother substitutes. Those 7 months or older, however, were disturbed at the separation.

Schaffer (1958) further reports the existence of two posthospitalization syndromes in these infants—a "global" and an "overdependent" syndrome. The global pattern of

behavior occurred mainly in infants who were under 7 months of age, whereas the overdependence was commonly found in those over 7 months. When these children returned home from the hospital, mothers of the younger infants reported that they exhibited an extreme preoccupation with the environment. For a lengthy period of time the child would engage in an unfocused inspection of his surroundings, rarely engaging in any other behavior such as vocalization or playing with toys. During this time the child was quite unresponsive to any person around him. Schaffer reports that some of the children also experienced somatic upset, in the form of feeding and sleep disturbances. Children who displayed the overdependent syndrome presented quite a different picture of behavior, with excessive clinging to their mothers and crying when left alone. This overdependence on the maternal figure was further revealed in a fear of strangers and the fact that familiar figures were sometimes regarded with suspicion. Thus we have support for the idea that early maternal-child separation has its effects not on the relationship between mother and child, but on behaviors which result from perceptual deprivation.

It is interesting that Schaffer describes the appearance of *both* syndromes in some children over 7 months of age, again indicating that maternal separation may have produced in them both perceptual deprivation and emotional upset as a function of the disruption of an established emotional bond. Schaffer explains the existence of the global syndrome in the following way. Piaget (1950) describes a level of cognitive development in infancy in which self and environment are merged. Schaffer suggests that under a condition of perceptual monotony such as exists in a hospital this natural tendency to merge with the environment is emphasized. When the monotony is reduced on the infant's return home the static perceptual field is disrupted. Such disruption is stressful and may cause somatic upset. Formation of a new perceptual field is necessitated and evidence of this is seen in the intensity with which the infant inspects his surroundings.

Increased Stimulation So far we have been concerned with the absence or, rather, severe reduction of general stimulation. But what if infants are subjected to stimulation in excess

of what they normally receive in the normal process of child-rearing? Some cross-cultural research is suggestive here (Geber, 1958, Geber and Dean, 1957, Whiting and Landauer, 1963). In assessing the development of a large number of African children, mainly from Uganda, Geber (1958) notes their extreme precociousness in the psychomotor area. From the first day after birth the African infant can keep his head from falling back when he is drawn into a sitting position and he can hold his back straight. In the first days of life he can focus his eyes (European infants are unable to do this until they are 8 weeks old), and by 6 weeks he can control his head, regardless of the position in which he is placed. At 4 months he can sit alone, at 8 months stand without support, at 10 months walk, and at 11 months use his thumb and forefinger accurately to pick up small objects. At each level he is 2 or 3 months ahead of the average development of a European child of the same age. In addition, Geber notes that these children display a lively interest in test materials, "talk" to the examiner, and smile in excess of what one would expect from their European counterparts.

This accelerated development Geber attributes to the massive stimulation which all infants receive from the time of birth. A Ugandan infant is never left alone by his mother but carried on her back, often with skin-to-skin contact, wherever she goes. In addition, he sleeps with her and is fed on demand by her. He is stimulated by her at her various occupations, hears all her conversations, is the subject of her warm and loving affection, and is often offered to others to hold. Geber suggests that the precocity she observed is not attributable solely to the advanced state of development of these children at birth. For children raised in the European way did not show a similar acceleration in development after the first month of life. Moreover, while most children were suddenly and dramatically weaned and often separated geographically from their mothers, with an accompanying reduction in social responsivity and liveliness, those who were weaned less suddenly maintained their lively behavior.

Landauer and Whiting (1963), having noted the effects of stress on physical development shown by studies with animals, located a number of societies in the Human

Relations Area Files in which various stressful procedures were involved in customary infant-rearing practices. These procedures included (1) pain, (2) shaping, usually for cosmetic reasons, (3) extreme heat, (4) extreme cold, (5) administration of emetics or irritants, (6) abrasion, for example, scraping with shell, (7) intense stimulation such as subjecting to loud noises, (8) binding, for example, painful swaddling. Adult males were, on the average, 2 inches taller in these societies than in societies where early stress was not imposed. The correlation between intensity and frequency of stress and male adult height was $+ .33$ ($p < .01$). In addition, the effects on adult stature seemed to be produced maximally during the first 2 years of life.

Gunders (cited by Whiting, 1965) noted that in the animal studies on stress, whenever animals were stressed or stimulated, they were taken away from their mothers for a variable period of time. Thus she hypothesized that a crucial factor might be an event associated with separation from the mother. Assessing separation in the first 2 weeks of life, based on amount of physical contact with the mother, handling by others, and use of a wet nurse, she found a correlation of $.53$ ($p < .01$) between separation and adult male height.

Landauer and Whiting did attempt to control for genetic, climatic, and nutritional variables in their study. However, we cannot discount the possibility that there is no causal relationship between early stress and adult height. It may be that stressful infant-rearing practices tend to occur in societies where hardship and stress are generally common. Thus, although early stress might not increase mortality rate, the general hardships of life might result in a strong selection against small size and physical weakness. Perhaps, too, early maternal separation, as defined by Gunders, might occur in societies where life is generally more difficult.

We do not yet know whether extremely massive stimulation is harmful. The animal data suggest it ought to be. But, so far, no researcher has reported the existence of child-rearing practices which subject a child to stimulation that is too great for optimal development.

Experimental Manipulation of General

Stimulation A few attempts have been made to test experimentally the notion that early perceptual stimulation, in the form of handling, rocking, and stroking, is important for human development. Hopper and Pinneau (1957) investigated the effects of additional stimulation on regurgitation. If Ribble was correct in suggesting that stimulus feeding decreases the incidence of gastrointestinal disturbance, they reasoned, these effects should be revealed in a decrease in regurgitation. Twenty-one mothers were asked to spend at least 10 minutes more than usual before each feeding: handling, rocking, swinging, rolling on the bed, fondling, tickling, and bouncing their infants. The diversionary explanation given to these mothers was that some experts feel such stimulation should be associated with an advance in speech development. At the end of 2 weeks the amount of regurgitation in the experimental babies was compared to that of the 21 controls who had not received the additional handling. According to the mothers' reports, although regurgitation was significantly reduced for both groups, there was no statistically significant difference as a function of the extra stimulation. Although the mothers supplied Hopper and Pinneau with data on incidence of vocalization, these are not reported.

More promising results have been obtained by Ourth and Brown (1961), White and Castle (1964), and Casler (1965). Ourth and Brown conducted their study in a hospital nursery with newborn infants. The 20 neonates in the experimental group were provided with extra handling at feeding time by either their mothers, the experimenter, or a nurse. This consisted of 60 minutes of firm support, fetal positioning, and mild, rhythmic stimulation, and was carried out, on the average, for $4\frac{1}{2}$ days. The experimental group, compared to a control group receiving routine care stripped of all unessential attention, cried less both immediately before and during feeding sessions. A somewhat inelegant feature of the design, however, was that all the experimental infants were breast fed while all the controls were bottle fed. Thus we might conclude not that extra handling reduces upset but that infants who are breast fed cry less than those who are bottle fed. Ourth and Brown suggest the infants in their control group were disturbed because of a sudden re-

duction in stimulation to which they had become accustomed as fetuses. For experimental babies the additional stimulation was more nearly like the kind and amount provided in the fetal environment by the walking, breathing, and changing position of the mother.

To assess the effect of handling on visual exploratory behavior, White and Castle (1964) gave infants in a state hospital 20 minutes of extra rocking daily for between 6 and 36 days. During rocking the infants' eyes were covered with a blindfold to control for a possible increase in visual experience. When they were tested at the age of 37 days infants who had been rocked spent a greater proportion of their waking time attending to and exploring their visible environment than did those who had not received the additional experience. There was no difference between the two groups in the development of prehension, rate of weight gain, or general health. The difference in visual attention gradually declined with time, probably because of the monotony of the visual surround, but both groups exhibited a sharp increase in visual attention at a time when they were relocated in a more complex environment.

Casler (1965) provided eight institutionalized babies with additional tactile stimulation beyond the amount ordinarily provided by the institution. The importance of this particular sensory mode was suggested to him, among other things, by Harlow's work on contact comfort. Children who were under 1 year of age at the beginning of the experiment, and who had given no indication that they were brain-damaged, received 20 minutes of stimulation, 5 days a week, for 10 weeks. The experimenter looked at the child's midsection, said "Hello, baby" every 60 seconds, and stroked any part of his skin not covered by clothing except the hands and mouth region. A control group was treated in the same manner except that the tactile stimulation was omitted. (The experimenter's verbalization was employed to keep the attention of children in the control group.) At the end of the experimental treatment all children were tested on the Gesell Developmental Schedule as they had been just before the beginning of the experiment. Both groups had declined, perhaps because of the deprivation of other kinds of stimulation in the institution. The decline of the experimental

group, however, except for the motor subtest, was one half that of the control. Thus the tactile stimulation seemed to have improved functioning in the areas of sensorimotor adjustment, eye-hand coordination, capacity to start new adjustments in problem situations, language development, feeding ability, self-dependence in play, and cooperativeness. It is unfortunate that interpretation of the results of this study are made difficult by the fact that the tactile stimulation was administered by a social agent. For it is possible that, if stroking is reinforcing, the experimenter who did it became secondarily reinforcing. The experimental subjects may then have been made more socially responsive, through stimulus generalization, to other adults around them. And this increased responsiveness might have been revealed in faster learning and better performance on a developmental test. The results of a study in which tactile stimulation is provided by a machine would, as Casler notes, be most interesting.

The Existence of a Critical Period for General Stimulation The existence of a critical period in animals for general stimulation has been previously documented. We have little evidence that such a critical period either exists or does not exist for humans. The only study which suggests that it might, at least for some functions, is that of Whiting and Landauer (1963). For additional evidence we must wait for more research.

Chemical and Nutritional Manipulations

Attempts to improve intellectual functioning by chemical means have been frequent and have generally been aimed at individuals functioning at the lower end of the intellectual continuum. But, except for mental deficiencies such as phenylketonuria, which result from known biochemical lesions, the results have not been promising.

Glutamic acid is the compound that has received the greatest attention as a possible agent for improving intellectual functioning. During the late 1940s and early 1950s innumerable studies appeared with the majority supporting the hypothesis that glutamic acid therapy has a beneficial effect on intellectual performance among the retarded. (These studies have been reviewed by Astin and Ross, 1960.) Most of the supporting studies,

however, suffered from methodological inadequacies, whereas those that were better designed were, almost without exception, negative in their results. Thus it is evident that a specific effect of glutamic acid on intellectual functioning has yet to be demonstrated.

Vitamins, particularly B₁ and E, have also received considerable attention in the treatment of mentally deficient children (e.g., Rudolf, 1950; Giudice, 1961). None of the reported studies, however, have included suitable control groups. Studies on the effects of tranquilizers such as chlorpromazine and reserpine, and of stimulants, have not suggested that these drugs facilitate intellectual functioning (see review by Louttit, 1965). Albert-Gasiorik and Aigrett (1961) administered chorionic gonadotrophin to sexually immature mentally retarded boys and found a small but statistically significant increase in intellectual functioning as compared with a group of placebo controls. They attributed the increase in IQ at least in part to an increased basic metabolic rate.

By far the most gratifying results in the chemical and nutritional treatment of mental deficiency have come from the investigation of phenylketonuria. Phenylketonuria is transmitted as a recessive characteristic from a single autosomal gene, and is associated with the excretion of phenylpyruvic acid in the urine and marked elevation in phenylalanine blood levels. These large amounts of phenylalanine reflect an inability to metabolize this amino acid, and are due to a block in the major route of phenylalanine metabolism, hydroxylation to tyrosine. Evidence suggests that the lesion is a marked deficiency in a liver enzyme, so that phenylketonuria may be considered primarily a hepatic disorder with the accompanying mental retardation a secondary effect (Udenfriend, 1961). The mechanisms underlying this secondary effect are unclear. Treatment consists of putting the phenylketonuric on a diet low in phenylalanine to reduce and maintain serum phenylalanine at a low level. If the diet is introduced during the early months of life the chances are good that the individual will develop normally. The longer the delay in instituting treatment, however, the less effective it will be (Lyman, 1963).

Enrichment and Restriction

Institutions do not provide a great deal in the way of general, massive stimulation. Institutions are deficient, too, in the kinds of *specific* learning opportunities they provide for their occupants. Clearly, much of the developmental and intellectual retardation described by Spitz, Goldfarb, and others is due to the restricted and unstimulating environments in which the children they studied lived.

Nor are unstimulating environments confined to orphanage and hospital settings. Retardation in home-reared children who are provided with inadequate learning opportunities in their own families has also been reported. Coleman and Provence (1957), for example, describe two children raised in deprived family settings who were retarded in growth, gross motor development, language, social functioning, and in the ways they reacted to people and toys. Clarke and Clarke (1954) indicate that mentally retarded children who come from poor and unstimulating homes show an increase in IQ once they are institutionalized. Children who come from good homes, on the other hand, do not show this change. It is evident that dogmatic statements about the ill effects of maternal deprivation often disregard the hazards a child may suffer from having a bad mother or an indifferent mother substitute.

In addition to looking at enrichment and restriction in institutional settings we shall also discuss the extensive literature on the effects of nursery school on child development. The preschool, with its emphasis on creativity and on the development of motor, language, physical, and intellectual skills, is a device favored by many to provide a child with a stimulating environment. The hope is that he will benefit from the experience with accelerated development and that this acceleration will have enduring effects. Some have cautioned that the good effects of nursery school may be offset by the harmful effects of maternal separation which preschool attendance necessitates. Glass (1949), however, found no support for the notion that nursery care for the child around 2 is harmful. She reports only slight differences in eating, sleeping, elimination habits, and behavior problems between children of work-

ing mothers who attended a day nursery for 6½ to 10 hours daily and a control group who were cared for at home by their own mothers. The slightly greater proportion of problem behavior in the nursery school children, she suggests, was due to the existence of problems in the home which probably caused the child's need for day care in the first place.

Heimicke (1956) compared two groups of 2-year-olds who were experiencing their first maternal separation. One group was composed of children in a residential nursery school and the other of children in a day nursery school. Children in the residential nursery tended to show greater and more prolonged upset at separation from their mothers. Some of them also refused to recognize their parents when they visited after an absence of 3 weeks. The children in the day nursery, on the other hand, reacted in a normal fashion to their parents when they came to take them home at the end of the day. Loss of sphincter control, hostility, active affection-seeking, and an increase in autoerotic behavior were observed in residential children. These behaviors were not seen in the day nursery children. On the basis of the two studies, then, we must conclude that the effects of short-term maternal separation which nursery school entails are nothing like those which longer-term maternal separation produces.

Institutionalization and Restriction of Experience The deprived environment of many institutions and the restricted opportunities they allow for learning have been discussed previously. Provence and Lipton (1962) describe at length the shortness of time spent in actual care of an individual infant and the lack of personalized care. Infants in the institution they studied were fed, changed, and bathed on schedule, regardless of any particular need state they might or might not be experiencing at the time. In her observation of institutional and home-reared infants, Rheingold (1961) reports that 44% of her observations were made while home children were being cared for. Only 15% of observations of orphanage children were made where they were receiving care. Home children received much more of certain kinds of stimulation such as being talked to, fed, and played

with. Orphanage children received the same kind of stimulation, but less of it. The two sets of infants spent equal amounts of time in play but had different kinds of toys. Home children were provided with a wide assortment of stimulating toys, whereas institution children were forced to resort to their own hands, clothing, and bars of their cribs.

The severe reduction in social stimulation which an institution provides has been emphasized by Zigler and his associates (Zigler, 1966) as a nonintellective factor affecting intellectual performance of institutionalized children. They suggest that a child who desires social interaction because he is deprived of it may modify his performance on intellectual tasks as a result. If being correct means a child's interaction with an adult will be terminated, he may continue to be wrong. The perseveration noted in institutionalized children (Green and Zigler, 1962) may also reflect this increased motivation for social interaction. Thus the conditions of social impoverishment in an institution may tend to make a child look dull. On the other hand, we would also expect that social deprivation could lead to faster learning where social reinforcement was made contingent on good and efficient performance.

Modification of the Usual Institutional Environment In a study of three Iranian orphanages Dennis (1960) notes the advantages of the better care which was given in one of them. In the deprived orphanages, conditions were similar to those we have described as typical. The children in these were retarded in sitting alone and in the onset of locomotion. Most of them, prior to walking, locomoted by scooting rather than creeping. In the third institution, however, the children were frequently handled, held in an attendant's arms while they were fed, propped in a sitting position, and frequently placed in a prone position. In spite of the fact that these children were probably initially more retarded than those observed in the first two institutions, their motor development resembled that of most home-reared infants.

Earlier, Dennis and Najarian (1957) had suggested that the poorer performance of orphanage children on the Cattell infant scale was due to their lack of opportunity for learning motor skills which the test demands. Den-

nis and Savegh (1965) reasoned that if orphanage children were accustomed to sitting in an upright position, if their interest in objects were encouraged, and if their skill in object manipulation were developed, then performance on the test should be much improved. Five days a week for 15 days they gave 1 hour's practice to institutionalized children in sitting and in watching and manipulating objects. This extra stimulation resulted in greater gains in developmental test scores by these children than by children who had not had the extra practice. Thus Dennis and Najarian's hypothesis was supported.

Rhemgold (1956) divided 16 6-month-old infants, who had been institutionalized for at least 3 months, into two groups. Children in the experimental group received all their care from the experimenter herself. For 7½ hours a day, 5 days a week for 8 weeks she fed, diapered, soothed, held, talked to, and played with them. The eight control children were looked after according to the routine of the institution, receiving their care from 17 different persons. They were also alone more, being cared for on only 7% of the time sample observations as opposed to 23% for the experimental group. On the Cattell and on tests of postural development and cube manipulation the experimental infants had slightly, but not significantly higher scores than the controls. They were, however, more socially responsive to the experimenter almost at once, and, with time, they became more responsive to other persons as well.

One year later the children, all but one of whom had left the institution, were tested for social responsiveness and developmental progress (Rhemgold and Bayley, 1959). The only statistically significant difference between them was that more of the experimental subjects vocalized during the social test. Thus, of the tested behaviors, only language development continued to be affected by the experimental manipulation. This fact suggests that verbal behavior may be more sensitive to the impoverishment of an institutional environment than are many other classes of behavior. Rhemgold, Gewirtz, and Ross (1959) have demonstrated that the vocal behavior of 3-month-old children can be increased by reinforcement in the form of smiling, auditory, and kinesthetic-tactile stimu-

lation. Presumably attendants in orphanages, unlike mothers caring for their own children, are much too busy to respond to the vocalizations of their charges with smiles and vocalizations of their own. In addition, they offer few stimuli that might evoke vocalization. It is surely this lack of care and encouragement—a reduction in learning opportunities—that accounts for so much of the language retardation of orphanage children.

An early study on the effects of increased stimulation in an institutional setting was done by Skeels and Dye (1939). They shifted infants and very young children from an orphanage to an institution for mentally retarded girls. Here these infants received considerable stimulation and attention from the mildly retarded older girls. These mother-substitutes became very fond of their charges and would even spend part of their very small allowances on them. They trained them in eating and toilet habits and taught them to walk, talk, and play with toys. At the end of 2 years the children had shown, on the average, a 27 point increase in IQ. A control group of children who had been left in the institution showed a decrease in IQ of 26 points.

Positive Effects of Institutional Care. Often institutionalization may provide some benefits. Home-rearing does not. The Hampstead Nursery (Burlingham and Freud, 1944) is a case in point. It provided wartime homes for children whose family life had been broken up temporarily or permanently because of the war. Although a residential nursery, it was not run in the usual institutional way. Rather, it tried to establish for its residents what they had lost, that is, the security of a stable home and opportunities for individual development. Burlingham and Freud report that infants between birth and the age of 5 months, when not breast fed under either condition, developed better in their nursery than in the average household. This, they suggest, was due to better food and air and the skilled and regular handling of the nursery staff. The nursery children between the ages of 5 and 12 months were more active in watching people and more responsive to their coming and going.² They showed greater develop-

² This increased responsiveness no doubt reflects the fact that the children were exposed less to adults than are children raised in family homes.

ment in muscular control in the second year of life than home-reared children because they were allowed greater freedom of movement and had more space to play in than home children. Finally, they were better eaters, probably because less stress was placed on eating in the nursery than is usually the case in a home. Parents are very concerned that their children eat properly and this concern produces problems. Among other things, it is possible for children to use eating, or noneating, as a way of effectively manipulating their mothers. Such avenues of manipulation are not open to a child in an institution, where no one really appears to care whether or not he eats.

Even with the enriched environment the Hampstead Nursery offered, however, its residents showed retardation in some areas of development. Children in the second half of their first year were less advanced in reaching out for objects and in active play. Their habit training was slow, probably because staff had less time to spend in intensive training, and many of them lost bladder and sphincter control when they were placed in the nursery. They were also retarded in speech development. Obviously, a child who is in a residential nursery is living in a community of nontalking playmates, where speech is of no immediate help to him in making known his needs and wants.

Between 1947 and 1950 a number of children from Kent were taken into the Meisham Reception Centre. Some were placed there after being removed from their own homes by court order. Others went because they were orphaned or, for some other reason,

Thus the appearance of an adult would have greater novelty value for them than for home-reared children. And this novelty would produce more orienting, attending, and investigatory behavior whenever an adult was in the vicinity. It is interesting that observers seem to categorize increased attending to people as either good or bad, depending on whether they are discussing the good or bad characteristics of institutionalization. According to their frame of reference, they may describe the observed behavior positively as "an increase in social responsiveness" or negatively as "an insatiable craving for affection," and "socially immature." That this increased responsiveness can be both facilitating and detrimental is evident from, among other things, our discussion of Zigler's work.

could no longer live at home. Rather than make decisions about placement immediately the authorities felt it better that the children be detained for a while in the center. There they could be given the beneficial experience of a healthier environment, and they could be observed for a period of time so that their needs could be assessed and more appropriate recommendations for placement could be made. Although it is obviously desirable to move a child as few times as possible, it was felt that the drawbacks of a stay in a residential nursery might be offset, in this case, by the benefits of more careful final placement. Unfortunately, since no control group of children who were not admitted to a temporary residential setting was assessed, the study can be considered only a demonstration and the reported results only suggestive. Lewis (1954), who studied the children 2 to 3½ years after final placement, suggests an improvement in the behavior of almost ¾ of the children. The children who had fared best were those placed in accord with the center's recommendation, either in a foster home, an approved school, or back in their own homes.

Institutionalization of Retardates There has been some controversy about whether children who display severe mental retardation should be institutionalized (see Centerwall and Centerwall, 1960, Birch and Belmont, 1961). Again, it seems clear that when the institution provides an enriched environment geared to the needs of its residents, including a stable relation to competent adult attendants, and when this environment is better than that provided for the child in his home, significant improvements in aggressive and pathological behavior and in intellectual development will occur (Tizard, 1960).

Nursery School as Enrichment Numerous attempts have been made to assess the effects, if any, of nursery school attendance on intellectual development. In addition, many investigators have been concerned with the effects of nursery attendance on social and physical development, emotional adjustment, and the learning of motor skills. Not all the studies have been methodologically adequate, for many of them have simply assessed the changes which have taken place over a period of time in children attending nursery school. The better designed studies have included a control group of children who have not at-

tended nursery school and also measured changes in their behavior over the same period of time

Much of the work on changes in intelligence has been carried out by investigators (e.g., Wellman, 1932, Skodak, 1939) from the Iowa Child Welfare Research Station, as part of a large-scale study of the effect of a number of different environmental conditions on intellectual development. In one study (Skeels, Updegraff, Wellman, and Williams, 1938) a nursery school was set up in an orphanage. Some of the children, who were retarded intellectually, socially, and in language development, were assigned to an experimental group which attended nursery school 6 hours a day. A matched control group was also selected from the orphanage population. The experimental group displayed a dramatic increase in IQ, whereas the control group did not. McNemar (1940) has criticized this study on statistical grounds, but a reanalysis of the data (Wellman and Pegram, 1944) has produced essentially the same results. Generally, consistent improvement in scores on intelligence tests by children attending nursery school has been reported by the Iowa investigators (Wellman, 1945). Moreover, this improvement seems to have been maintained over time. Woolley (1925) and Starkweather and Roberts (1940) have also reported gains in IQ by children attending nursery school at the Merrill-Palmer School in Detroit.

Other studies (e.g., Anderson, 1940, Jones and Joergensen, 1940, Goodenough and Maurer, 1940), however, have not shown these beneficial effects of nursery attendance. Accordingly, the Iowa studies have been criticized. It has been suggested that the children had been coached by parents or nursery school teachers, that they had been tested so often that they had become practiced at taking IQ tests, and that the testers had been biased by their knowledge that the child was attending nursery school. These criticisms cannot be applied to all the studies, however. For example, in many of the studies the controls had been tested as often as the children who had attended nursery school. Triax (cited by McCandless, 1967) has shown that children without siblings are the ones who gain in IQ in nursery school. It seems that children who have little opportunity to play with other children lack the intellectual and

social stimulation provided by a preschool experience. And it is unlikely that examiner bias would operate differentially between only children and those with siblings.

It is a rather time-wasting exercise, as Triax' study reveals, simply to compare children who have gone to nursery school with those who have not. Any observer is aware of the very large differences that exist between nursery schools. Some offer genuinely enriched and stimulating environments to children who attend. Others are little better than glorified baby-sitting establishments. In most cases there are differences in attitudes and child-rearing practices between parents who want their children to go to nursery school and those who do not. These differences almost certainly mean that children who are tested in a nursery school and children in a control group are not from the same general population. This is not an appropriate criticism, of course, where children are randomly assigned to a preschool and a control group, but this is a condition which can only be met when children are living in institutions. If a child is not doing well in nursery school he may be withdrawn. Thus only those who are improving in performance are left to be tested by the psychologist. Even the most enriched preschool experience may have no effect on a child if he already comes from a very stimulating home environment. Again, the experiences which have proved beneficial for a middle-class child may not be those which will benefit a lower-class child. The deprived child may lack the experience that would enable him to benefit from the conventional nursery experience.

The preschool experience's influence on social development has also been assessed by many (e.g., Jersild and Fite, 1939, Hattwick, 1936, Brown and Hunt, 1961). Again the results are discrepant. These differences may be partly due to the diverse measures of "social adjustment" used by investigators.

It is clear that a more fruitful approach to assessing the effects of preschool attendance will come from research which relates these results to a specific aspect of the nursery experience. These aspects include the physical setting, the program, teacher-child relations, peer-group interaction, and personality characteristics of the individual child. Studies which do this have recently been reviewed by

Swift (1964) In essence, the studies suggest that a program's effectiveness depends on its appropriateness to the child's developmental level and the provision of experiences which supplement instead of duplicate those he is receiving elsewhere The teacher's qualities are extremely important She must actively engage in teaching the child new intellectual and social skills The child's ability to utilize the peer-group aspect of the nursery experience depends on his age, temperament, and the experiences he has at home

Education of Culturally Disadvantaged Children Recent concern with the education of culturally disadvantaged children has produced attempts at detailed analysis of what an enriched or deprived environment may involve for a given child Thus people have begun to try to understand the mechanisms whereby cultural deprivation impairs cognitive capacities and academic achievement Hess and Shipman (1965), for example, argue that the control which mothers in deprived families employ restricts the number and type of alternatives for action and thought that are open to their children These mothers use "restricted" rather than "elaborated" styles of verbal behavior (Bernstein, 1961) They say "Shut up" rather than "Would you keep quiet a minute? I want to talk on the phone" Thus the child does not have the opportunity to reflect, consider, and choose among alternatives for speech and action He develops modes of behavior that are impulsive rather than reflective, present- rather than future-oriented, and disconnected rather than sequential

In an analysis of the differences in cognitive functioning, linguistic functioning, and mother-child relationships among four different social status groups, Hess and Shipman conclude that deprivation means an environment in which behavior is controlled by rules rather than attention to individual characteristics of a given situation and where no attempt is made to teach a child about the relationships between two events "This environment produces a child who relates to authority rather than to rationale, who, although often compliant, is not reflective in his behavior, and for whom the consequences of an act are largely considered in terms of immediate punishment or reward rather than future effects and long-range goals" (1965, p

885) Presumably, a preschool program should be designed to develop in a child those behaviors which this kind of child-rearing makes difficult

More precise analysis of deprived environments has led to the creation of a number of research projects concerned with the effects of preschool environment on culturally disadvantaged children Gray and Klaus (1965) describe the culturally disadvantaged child in the following terms They suggest that he receives less reinforcement for his behavior, especially from adults, that the reinforcement he does receive is probably not verbal, that he is urged "to stay out of trouble," and that the reinforcement he does get is diffuse rather than focused precisely on the adequacy of his performance This last contention is supported by the findings of Zigler and Kanzer (1962) As a result, only a small part of the behavior of these children is under the control of adult verbal direction, then exploratory tendencies are inhibited, and, in general, they are not responsive to verbal reinforcement Zigler and de Labry (1962) have also found that lower-class children are not motivated simply by being correct They learn as rapidly as middle-class children, however, if they are given material reward On the basis of their analysis Gray and Klaus have concentrated in their program on studying the development of attitudes to and aptitude for school achievement, the development of delay of gratification, some aspects of perceptual development and cognition, and language

Both Gray and Klaus (1965) and Deutsch (1962) have worked with parents, as well as with children, in a "total push" program Hodges, McCandless, and Spiker (1966), on the other hand, have developed a program to which only children are exposed So far, the results of these experimental programs have been encouraging, with at least early gains in IQ reported McCandless (1967), however, reports his impression that children given enriched training continue to improve only if they stay in demonstration programs or are placed in schools that enroll children from all socioeconomic levels If they are returned to a school where the students come from an equally impoverished background, they lose their initial momentum Teachers in this situation, appalled by the lack of essential skills possessed by the majority of their students, ap-

parently tend to concentrate on this majority and to ignore those from the demonstration school projects. Hence students from such projects coast and rapidly lose their initial advantage.

Manipulation of the Social Environment Social Development in Humans

The Development of Social Attachments: A Learning Analysis In order to understand the effects of maternal separation *per se* we should first understand the development of social attachments under normal conditions. For some time the popular method of accounting for this development involved an emphasis on the mother-child feeding relationship (e.g. Sears, Maccoby, and Levin, 1957). Because the mother's presence was always associated with the reduction of primary drives, particularly hunger, she supposedly acquired secondary reinforcing properties. Thus the child found her reinforcing, that is, he became attached to her. The emphasis on the feeding situation, almost to the exclusion of other situations in which mother and child interact, was dictated primarily by psychoanalytic theory and its concern with the oral drive.

Sucking as the *basic* response underlying social attachment has recently been questioned. Human infants during the first 1½ years of life frequently form specific attachments to individuals who never participate in routine caretaking activities (Ainsworth, 1963; Schaffer and Emerson, 1964b). Harlow's work, discussed elsewhere in this chapter, has demonstrated that contact comfort is a more important antecedent of attachment, at least in rhesus monkeys, than is feeding. The question of the importance of contact comfort or clinging in the development of human social responsiveness, however, remains unanswered. It is certainly clear that human mothers present a surface to their infants that is less supportive of clinging than do mother rhesus monkeys. Clinging does not generally appear in infants until *after* specific social attachments have been formed. It seems to become more important when the child becomes mobile, at which time he frequently clings to his mother's hand or skirts. Rheingold and Keene (1963) have observed that the human infant contributes much less to his own transport than do many other mammalian young, that

is, he hangs on less. Schaffer and Emerson (1964b) also report that infants whose mothers employ much physical contact in interacting with their children are no more attached than infants whose mothers rely primarily on other means. These include stimulation by their voice and facial expressions or diversion of attention from themselves through the provision of toys, food, and other objects whenever the infant demands attention.

Rheingold (1961) indicates that a basic and primary activity of the human infant is his visual exploration of the environment. Certain objects attract and hold his attention and the more interesting of these evoke facial, vocal, and bodily responses of delight. The reinforcing effectiveness of complex and changing stimulation has frequently been documented (e.g., Beelyne, 1958). One of the most interesting objects in the infant's environment, from the standpoint of complexity, is the human face, with its shiny and non-shiny surfaces, its bumps and contours. Hence we would expect that a face would be even more likely than other objects to elicit vocalization, smiling, and reaching out—all behaviors which are considered indicants of social responsiveness. Furthermore, unlike stuffed teddy bears and rattles, human faces generally respond to a child's evident delight by changing expression and vocalizing. Thus the child's social behaviors may be further increased in frequency by reinforcement through this stimulus change. In addition, the infant quickly discovers that it is the humans in his environment who are capable of providing him with stimulation and stimulus change from inanimate objects. They are the ones who move his carriage, who carry him around, who turn on the television, and who dangle various toys in front of him. Evidence supporting this hypothesis that distance receptors may play a more important role than feeding or clinging in the development of social responsiveness in human children has recently been summarized by Walters and Parke (1965).

Schaffer and Emerson (1964b) suggest that there are three stages in the development of social responsiveness. In the first the infant finds that he can receive stimulation from all parts of his environment. In the second he discovers that humans are the best providers of

stimulation This is a phase of indiscriminate attachment where the presence of *any* human will alleviate his distress at social isolation The third phase, that of specific attachments, begins at the age of 7 months It is only at this age—Piaget's sensorimotor stage IV—that we see the beginning of object conservation Before this a specific social object has no meaning for the infant apart from its presence, and so it is not missed in its absence Upset at separation from the mother, Schaffer hypothesizes, begins only at an age when the infant begins to search for objects that have been removed from his perceptual field That 7 months is the point where specific attachments are formed is evident from data provided by Schaffer and Callender (1959) Children hospitalized after 7 months bitterly protest separation from their mothers and cling to them during visits They display negativism toward hospital staff and are frightened of them This behavior is interspersed with intervals of withdrawal and subdued behavior Infants hospitalized before 7 months of age do not protest separation They accept strangers as mother-substitutes without a change in their usual level of responsiveness (except for a noticeable absence of vocalization), and they adjust to radically different feeding routines with no apparent difficulty

Schaffer (1963) provides evidence indicating that a phase of indiscriminate attachment is necessary before specific attachments can be formed He compared two groups of hospitalized infants Members of one group received very little stimulation, although they were visited by their mothers The second group's members had been exposed to tuberculosis and were institutionalized for vaccination This group received a great deal of stimulation from the many nurses who cared for them, although they were not visited by their own mothers All the children were at least 30 weeks of age when they were reunited with their mothers Those in the first group who had received little social stimulation took much longer to form a specific attachment to their mothers than did those who had received a great deal, even though this stimulation was not from their own mothers Thus it would appear that general social stimulation must be provided before specific attachments can be formed Prolonged exposure to the individual with whom the specific at-

tachment is eventually formed is not necessary Only the total amount of stimulation appears to be important

Differences in social responsiveness between home- and institution-reared infants are especially understandable in terms of deprivation of social stimulation Rheingold (1961) found 3- and 4-month-old infants in institutions were more socially responsive to a strange experimenter than were home-reared children The institutionalized children gave the observer more consistent attention, smiled more readily at her, smiled, vocalized, and reached out toward her more often, and gave her fewer negative responses Over the period of observation they vocalized with increasing frequency, whereas home children decreased their frequency of vocalization The institutional children were certainly more deprived of social stimulation than are home-reared children The high frequency and intensity of their social responding would seem to reflect this deprivation They may also have been learning that strong responding was necessary in order to keep an adult near them In addition, home-reared children probably were able to discriminate between their own mothers and a strange observer Since many of the positive cues generally associated with the mother would be missing, the strength of their accustomed responses would be diminished A child raised in an institution by a number of different caretakers could not so easily discriminate a stranger from a non-stranger The increased social responsiveness in institutional children in the form of prompt attention when anyone entered their nurse's and the poor discrimination between a regular attendant and a stranger's face have also been noted by Provence and Lipton (1962)

Smiling at a stationary, unsmiling human face does not occur in institutional infants until they are around 14 weeks old, and it reaches its maximum at 17 to 20 weeks of age Home-reared children smile much earlier (6 to 10 weeks), with modal smiling occurring between 11 and 14 weeks (Ambrose, 1961) Smiling is probably more frequently elicited and reinforced among home-reared than institutional children, hence its earlier appearance Again, home-reared children may learn to discriminate sooner between a familiar and a strange face Thus they would sooner cease smiling at a face that had not

been associated with reinforcement in the past

Imprinting and the Development of Social Attachments As indicated earlier, the similarity between imprinting and the development of social attachment in human infants has led a number of investigators to treat them as identical processes. Gray (1958) suggests that smiling in human infants is the motor equivalent of following responses in animals below the higher primates, whereas Caldwell (1962) proposes that the motor equivalent is the visual following response. Scott (1963b) maintains that any response which leads to prolonged contact with the maternal figure at the proper time will be important in the development of social attachment. He also indicates that an intense emotional experience, whether rewarding or punishing, will increase the formation of attachment. Thus Fisher (1955) found that puppies displayed attachment to a human with whom they had had only painful physical interaction if no other social contact was made available to them. We are reminded here of the observation (Lewis, 1954) that some children who have been severely neglected by their parents still display concern for those parents. It is also true, however, that, although the material needs and social training of these children have been neglected, they have generally received affection from their parents. Similarly, although Fisher punished his dogs, he may also have provided some gratification for them in the form of perceptual stimulation.

Bowlby's (1958) analysis of the attachment process is also greatly influenced by the work of ethologists. He suggests that sucking, clinging, and following are instinctual responses which keep an infant in close contact with his mother. These unlearned behaviors mature at different times during the first year of life and thus are centrally important at different times. In addition, crying and smiling on the infant's part serve to elicit maternal behavior from the mother, toward whom they are directed, and thus keep her in her infant's presence. Bowlby, however, does not present the conditions for attachment in a way that suggests that learning is not involved. Using certain assumptions from associative learning theory, Cairns (1966b) has proposed that mammalian attachment behavior is determined solely by the length of association with

an object in a given context and the relative cue weight of the object. Certainly this is an alternative conceptualization to a secondary reinforcement theory which must be considered.

If there exists a critical period for imprinting it seems too that there could well be a critical period for the development of social attachment in humans. Gray places it between 6 weeks and 6 months, beginning with what he suggests is the onset of learning ability, continuing with the smiling response, and ending with the development of fear of strangers. A similar position is taken by Scott (1963b). Although the period of 6 weeks to 6 months—the "period of primary socialization"—is critical for the formation of social relationships, Scott suggests that later ages are also critical with regard to psychological damage resulting from breaking off these relationships. The word "critical" now begins to lose much of the meaning with which it has been generally endowed.

Imprinting is a phenomenon whereby an organism learns to make social responses to objects to which it has been continually exposed. In nature this is usually to its own species, and it does not refer to attachment to a particular member of that species. Hence we are left somewhat in the dark as to whether there is a critical period for a generalized, nonspecific attachment to the human species, or whether it is for *specific* attachment to a given individual or individuals. Again, the idea that a developing fear of strangers marks the end of the socialization period is made rather less satisfactory by the finding that stranger anxiety is *not* in a one-to-one relationship with either attachment or separation anxiety (Ainsworth and Wittig, in press; Ainsworth, 1963; Benjamin, 1963; Schaffer and Emerson, 1964b; Tennes and Lampl, 1964). Children who are attached may display no fear of strangers. Again, a fear of strangers may occur in a child before he actually develops a specific attachment. The intensities of the two phenomena—attachment and fear of strangers—do not coincide. Clearly, at the moment, the critical period hypothesis needs further clarification, as do the developmental mechanisms which might be involved in it.

Situations in which the Formation of Specific Attachments Is Impeded Infants in institutions are obviously deprived of the oppor-

tunity to form a specific attachment to a single caretaker. If, for present purposes, we adopt a secondary reinforcement theory, we may also say they have less chance to learn that people in general are reinforcing because they receive less caretaking. If the responses they make to social stimuli are not reinforced, these responses may, through habituation, soon disappear. Under normal rearing conditions most children must also learn to make certain operant responses like crying or reaching out in order to receive certain gratifications. If caretaking in an institution is given so that the child has no control over what happens to him—if reinforcement is not contingent on anything he does—he may soon appear quite socially unresponsive. All these conditions are encompassed in a description by Ainsworth and Wittig (in press) of the variables in mother-infant interaction which seem to foster both the growth of healthy attachment and of competence. These include (1) frequent and sustained physical contact, especially during the first year of life, together with the mother's ability to soothe her infant's discomfort through physical contact, (2) the mother's sensitivity to her baby's signals and her ability to time her interventions with his rhythms, (3) an environment where the infant feels he has some control over what happens to him, (4) the mutual delight which mother and baby take in their transactions with each other.

Institutions vary in the extent to which they support social responsiveness and competence. Even where attempts are made to provide intensive and personal care, however, the quality of emotional interchange may be limited. Nurses are reluctant to become too involved with children from whom they know they will be separated (David and Appell, 1961). The institution Rheingold (1961) studied was supportive to the extent that its occupants were socially responsive to a stranger. Others may provide less optimal conditions for learning. Provence and Lipton (1962) describe an institution in which the children showed little cooing or crying in response to people, where they showed a decreasing tendency over time to reach out for or move toward people and toys, and where they displayed no playful activity with others. The children were generally bland in affective expression and unafraid of strangers. When they

were in distress they failed to turn to an adult—they gave no sign that they anticipated or expected that a need would be met. If something unpleasant was being done to them they only cried miserably, but made no attempt to push away from the noxious event. In this institution, whose environment is described in extensive detail in the report, there was an absence of specific maternal care, very little time was spent in actual care, and none of it was personalized. Children were fed and changed, not when they wanted it, but according to routine. Many of their distress signals went unanswered so that opportunities for learning the source of comfort were few. Feeding, diapering, changing of position, and being given a toy were done on schedule. Only occasionally were these related to the child's wishes. Clearly any behavior which the child might use to gain attention was extinguished, since care was independent of anything he did. And any secondarily reinforcing qualities adhering to caretakers must have been quite minimal in light of the restricted caretaking that was provided.

Provence and Lipton also report that the children were atypical in their approach to toys. They showed no preference for one over another, were not displeased at the loss of a toy, and made no attempt to recover it. They suggest that a normal infant invests toys with some of the feeling he has developed for his mother. Presumably, feelings of attachment to a mother might generalize to an inanimate object. It is also possible, however, that the impoverished environment offered by the institution produced retardation in the development of the concept of object constancy. These children may have been behaving like younger ones who, when a toy disappears from their surroundings, act as if it no longer exists. The children also rarely displayed any self-stimulating activities, except for rocking. Thumb-sucking and the mouthing of toys and other objects were rarely observed. Perhaps a mother must first make a child aware of the gratification of tactile stimulation before the child himself will reproduce it.

Provence and Lipton suggest the effects of institutionalization on social behavior are irreversible. Although the children improved dramatically after foster home placement, they were still impaired in utilization of the mother as a source of comfort, relief from tension,

and help in problem-solving. They were indiscriminately friendly, and had problems in impulse control and ability to delay gratification. It may well be that the critical period for the establishment of emotional ties to a single individual had passed. Without a specific emotional attachment the internalization of parental standards is difficult, both because the process of identification with parental prohibitions is weakened and because the child has no need to maintain parental approval by performing the behaviors they want him to. On the other hand, it may be that there still had not been sufficient learning opportunities for impulse control and seeing the mother as a source of gratification by the time of the follow-up. These would be opportunities the children had been almost totally denied in the institution. Then, too, adults may find it difficult to tolerate a social behavior in an older child which they would accept and try to modify in a younger one. Thus foster parents may not provide the same learning conditions for older children from an institution that they would younger children. Again, the explanation may be a genetic one. As we have suggested earlier, children in an institution probably do not constitute a random sample from the general population. The genetic constitution of the children Provence and Lipton observed may have predisposed them to display aggressive, uncontrolled behavior.

One of the features of institutional care is that it provides interaction with many caretakers. Even if an institution's conditions were such as to provide excellent conditions for the learning of social behavior, it might be that the diffusion of attachment over a number of individuals could be detrimental to optimal behavioral development. If a young organism does not learn the components of an emotional attachment to a single mother-figure, he may have difficulty in forming anything but superficial attachments to others. Hence the indiscriminate friendliness which Goldfarb, Provence and Lipton, and others have noted.

Studies of children raised in Israeli kibbutzim are relevant here. From early infancy these children are placed in a nursery where they are cared for, along with a number of other children, by a substitute mother-figure, the *metapelet*. The *metapelet* is responsible for the everyday care and training, including impulse control, of the children. Their own

mothers, who visit regularly and may even breast-feed their children for several months, seem primarily responsible for affectional gratification. Rabin (1958) found some evidence for developmental retardation among infants in the kibbutzim, which he attributes to a lesser total amount of stimulation than is ordinarily provided in family homes. Studies at later ages, however, suggest that these children are in no way retarded intellectually nor do they display any personality distortions. Rabin suggests they display better emotional control and greater maturity and ego-strength than children raised with their own families. There has been some suggestion that children who have lived all their lives on a kibbutz tend to lack emotional depth. Although they are capable of maintaining satisfactory relationships with their peers, there is a tendency for all relationships to be on the same level. It may be true, then, that one must learn how to form an intense emotional relationship with a single mother-figure before intense relationships with others can be formed in later life.

Other data on multiple mothering have been provided through the study of children in home-management houses—training centers for students of home economics. Typically, many students provide care, in turn, for these infants before they are placed in foster or adoptive homes, usually within 5 or 6 months. There is always a house mother available who provides some continuity in mothering. Follow-up studies of these children, at least in the preschool years, suggest no damage to them as reflected in their response to frustration or brief maternal separation (Gardner, Pease, and Hawkes, 1961) or in personality development (Gardner, Hawkes, and Buchman, 1961).

In a study comparing children raised in "monomatric" families (where the mother was the exclusive caretaker of her infant) with those reared in "polymatric" families (where the infant was cared for by more than one person), Caldwell et al. (1963) found no difference between the two groups of children at 6 months of age. At 1 year, however, the infants from the monomatric families were more active, more emotionally dependent on their mothers, and more emotional in their interactions with their mothers. Mothers in monomatric families, however, had earlier been found to be more affectionate, active, sensu-

ous, playful, and vocal with their infants, and more concerned with their well-being than mothers in polymatric families. Thus the observed differences in the behavior of the two groups of children might well have been due to their mothers' personality differences, rather than to the number of caretakers with which they were provided.

An unusual study of six German Jewish orphans (Fleud and Dann, 1951) provides evidence that lack of a consistent mother-figure is not necessarily detrimental to the formation of social attachments. After their parents had been killed, these children had arrived at the same concentration camp when they were a few months old. After that, they were always together as a group. Because they were in a deportation camp their caretakers changed very often. When they were taken to England they were observed to have a most unusual emotional dependence on each other. All their positive feelings centered exclusively on their own group, where there was almost complete absence of jealousy, rivalry, and competition. Since they had experienced most of their satisfactions in each other's presence, they appeared to have developed the kind of attachment for each other that children raised in more normal environments have for their own mothers. Moreover, they soon came to make positive approaches to the adults who continuously looked after them in England. These responses were very similar to the approaches they made to each other.

Maternal Separation after a Specific Attachment Has Been Formed. The reaction of a child over 6 months of age to separation from his mother has been described by a number of observers (Bowlby, 1958, Robertson and Bowlby, 1952, Roudinesco, David and Nicolas, 1952, Spitz and Wolf, 1946). Typically, there are three stages. The first involves active protest and entails much crying and physical agitation. The second stage is one of despond with withdrawal and monotonous crying. The final stage is one of detachment. Here all adults are treated socially but casually and on the same level. The child appears preoccupied with material things and no longer seems to care for anyone. It is notable that the first two phases do not appear where the relationship with the mother has previously been severely impaired.

Gewirtz (1961) offers an explanation of

this behavior in keeping with a learning analysis of the development of social attachment. He points out that maternal separation involves an abrupt and continuing change in what was earlier a satisfactory pattern of availability of cue and reinforcing stimuli to the child, after these have been conditioned as such for him. The initial response to this change is frustration—an increasing rate of responding and the emergence of emotional responses which are incompatible with the development of new and desirable responses. If the new caretaker is not able to respond to and provide reinforcement for what socially adequate responses the child may produce, these will soon extinguish. We might also suggest that the younger the child, the more restricted his behavioral repertoire and hence the greater his difficulty in producing new and acceptable responses. A period of depression at the loss of a valued object may be followed by apparent recovery from grief. The social detachment the child displays during this phase may well result from the repeated experience of becoming attached to a nurse who eventually leaves. After this happens a number of times, the child no longer becomes upset at separation from a caretaker.

What damage, if any, does a child experience from maternal separation after a specific attachment has been formed? Freud and Burlingham (1944) report that children who were separated from their families and placed in residential nurseries during World War II showed a great deal of initial disturbance, but they also point to the possibility of minimizing personality damage by providing substitute individualized relationships. In a follow-up study of 20 adults who had been placed in residential nurseries as children during the war, Maas (1963a, 1963b) found no severe cases of personality pathology. Most of these adults were functioning very well. There was a trend in the data, however, suggesting that separation was more damaging to children less than 1 year old than to those who were more than 1 year old. The former showed a greater incidence of disturbance in the personality-social area as adults. Bowlby, Ainsworth, Boston, and Rosenbluth (1956) report that children who had spent some time in a tuberculosis sanitarium before 4 years of age did show tendencies toward withdrawal, apathy, and aggression. They did not, how-

ever, show a disturbance in their capacity to establish relationships with their peers. In summary, then, the data do not suggest that every child who is separated from a figure to whom he has become attached will suffer irreversible damage. That some damage may occur, if the separation is not handled well and a suitable new environment is not provided, cannot be ruled out.

GENOTYPE AND EARLY EXPERIENCE

As we have suggested, any change in an organism's behavior produced by some environmental manipulation must also be conditioned by its genotype. Depending on how the genotype is constituted, an early experience may have a large effect or no effect at all, one that is permanent or one that is transient. Behavior, like any other character—morphological or physiological—has hereditary determination at least in respect to many of its formal measurable aspects.

It is obvious enough, of course, that many of the *content* aspects of behavior depend completely on environment, for example, the fact that one person speaks German and another Russian. However, the ease with which one individual, as compared to another, learns to speak a language (either as a native language or a foreign one) may be heavily influenced by genotype. Learning ability, in other words, is probably inherited. Evidence for this conclusion comes mostly from animal studies using both the method of selection and the method of strain differences (see Fuller and Thompson, 1960, Hirsch, 1967).

Since early environmental experiences must be retained by some learning or storage mechanisms, we may expect to find that the susceptibility of an organism to change as a result of environmental manipulation should vary according to genetic constitution. That is, some individuals may be expected to be strongly buffered, others weakly buffered.

Empirical evidence bearing directly on this point has been put forward by a number of workers. Hughes and Zubek (1956), using the McGill "bright" and "dull" rat strains selected by Thompson (1954), were able to show that dulls much more than brights showed improvement in maze performance as a result of glutamic acid treatment during infancy. A subsequent study by the same au-

thors (Hughes and Zubek, 1957) further demonstrated that the effect produced was fairly long and lasting, extending over a period of several months. Hughes and Zubek (1956) suggested that possibly dullness was due to a selected metabolic error relating to neural functioning and ACh activity for which exogenous glutamic acid provided some compensation.

Genetically selected maze ability is also differentially responsive to early environmental—as against chemical—manipulation. Cooper and Zubek (1958) were able to show that dulls gain much more than brights in Hebb-Williams maze ability as a result of exposure to enriched early experience. In a restricted environment, however, brights lose much more than dulls. These data are summarized in Table 3. They show that both strains are

Table 3 *The Effects of Enriched and Restricted Environmental Rearing on Maze Performance in "Bright" and "Dull" Rats (McGill Strains) Hebb Williams Maze Error Scores Are Shown*

	Rearing Conditions		
	Normal Cage	Enriched	Restricted
Bright	117.0	111.2	169.7
Dull	164.0	119.7	169.5

equally susceptible to phenotypic changes but only in one direction. This presumably means that selection produced animals representing, respectively, the upper and lower limits of rat intelligence.

A study bearing more directly on this point was carried out by Thompson and Olian (1961). This has been referred to previously. Briefly, the data showed that the effects of administration of adrenalin to pregnant mice of three strains had effects on offspring activity level that varied with genotype. Offspring from the normally high-active strain—C57-BL/6s—showed reduced activity, those from the usually low-active A/Jax mothers showed increased activity over controls, and those from BALB/Ci mothers were not altered. These results suggested that the BALB genotype is rather strongly buffered as compared to the C57 and A/Jax genotypes. The general finding that an early treatment tends to increase the activity of the less genetically

active strain and lower that of the genetically more active strain has been confirmed by DeFries (1964) and DeFries and Wen (1964). It is of some interest to note, however, that in the DeFries study C57s were the more active, but in the DeFries and Wen study BALBs were the more active strain under control conditions. This was ascribed to differences in the testing situation used in the two experiments. Whichever strain was the lower-active showed the increase as a result of treatment and whichever was the higher-active showed the decrease. Finally, DeFries (1964) showed that hybrids, which were normally more active than either of the pure strain animals, responded differentially to prenatal stress depending on the genotype of the mother. This involvement of maternal as well as fetal genotype was further demonstrated by DeFries, Wen, and Hegmann (1967). They studied effects on offspring activity of exposure of pregnant mothers to cold, shaking, noise, or adrenalin chloride. Differences in activity-level were found between the effects of physical and those of chemical stress. The two types of stress also interacted differently with genetic factors. The results of the studies outlined above as well as those of other investigators (King and Eleftherion, 1959, Lindzey, Lykken, and Winston, 1960, Levine and Wetzel, 1963, Levine and Broadhurst, 1963, Lindzey and Winston, 1962, Henderson, 1966a) indicate clearly that genetic differences exist with respect to buffering.

At the human level, fewer data are available. It was suggested by Kallman (1953) that schizophrenia—a syndrome he considered to be dependent on a single recessive gene—could be expressed or not depending on what he called a nonspecific constitutional defense mechanism having itself a polygenic basis. Thus a homozygous recessive individual might manifest schizophrenia in response to severe stress or not, depending on the strength of the defense system. A similar notion has recently been put forward—albeit in somewhat different terms—by Meehl (1962). This writer hypothesized that the various symptoms of schizophrenia will always appear in what he designated as the schizotaxic person, who carries the genes for the basic neural-integrative defect underlying the disease, provided there is also exposure to an

unfavorable environment, and provided also that there is a low inherited capacity for resistance to stress. If these conditions are not all fulfilled, according to Meehl, schizophrenia will not appear, although the basic personality organization underlying it may be manifested in a well-compensated form. These ideas have received a good deal of support from Gottesman and Shields' (1966) analysis of their own and other workers' data. They conclude that a large proportion of cases of schizophrenia may be polygenically determined, the expression of the disease depending on the number of genes present and also on the amount of environmental stress. It would be useful to have further data implicating early experience variables.

These are interesting notions and intuitively make sense. It does indeed seem likely that many individuals who have a basic inherited disposition to some abnormality and who are exposed to environmental stress favoring its expression may still be protected by some secondary defense system which is itself also genetic. Unfortunately, however, no conclusive data directly bearing on such an assertion are available. One set of observations made by Bentley Glass a number of years ago (1954) is perhaps suggestive of the kind of work that badly needs to be done. His interest was in what he called "adaptability," the process by which living organisms make appropriate adjustments to changing environmental conditions. It is a concept similar to "buffering" but of a more evaluative character. To study it empirically, Glass observed the responses made by members of identical twin pairs in a visual-motor task—hitting a target with a needle—under normal conditions and under conditions of mild stress. The mild stress consisted simply of the ingestion of five cups of hot or cold coffee. Some of Glass' data are summarized in Fig. 13. The plots indicate a striking qualitative and quantitative similarity between twins under both the normal and stress conditions. This suggests that "adaptability" or responsiveness to some environmental treatment is indeed genetically conditioned. Obviously, as Glass himself has pointed out, these results are very preliminary and more data will be needed before any firm conclusions can be drawn. Nonetheless, the method seems to

Fig. 13 The similarity of effects of a mild stress on visual-motor performance in a pair of identical twins. In the left graph, Albert drank the coffee, in the right one, Andrew drank it (Glass, 1954)

be capable of shedding considerable light on the problem we are discussing.

Granting that buffering and adaptability are genetically based, we may still inquire as to the exact nature of the genetic mechanisms involved. Lerner (1954), in a discussion of this problem, has suggested two main possibilities. First, it may be a property of degree of homozygosity—either in general or at specific loci. That is to say, it may have to do with heterosis or hybrid vigor. Data gathered by Winston (1964) give quite direct support to this alternative. This investigator compared the amount of behavioral change induced by early sound trauma in inbred mouse strains with the amount produced in hybrids between them. The hybrids turned out to be less readily influenced than the parental strains—a result which the author ascribed to heterosis.

On the other hand, there is the second possibility: buffering may be caused by particular genes at specific loci. The cogency of this notion is suggested first by the fact that differences may readily be found between inbred strains which are not known to differ in degree of heterozygosity. Indeed, if such differences do exist, it is unlikely they could be large enough to exert very much influence. Furthermore, it has been shown that buffering may be a character susceptible to selection. Smes (1959, 1961) was able to select a strain of rats that showed higher susceptibility to stomach ulcers following stress. The

females of the susceptible line showed, over the three generations of selection (up to F_2), a more rapid response, the percentage of individuals manifesting ulcers rising from 68% in the base population to 96% in the F_2 generation. It is not certain, however, whether this result was due to fixation of specific genes or to loss of heterozygosity. In the absence of either control or nonvulnerable lines, no firm conclusion can be drawn concerning the genetic mechanisms involved in the specific case of buffering. A long-term project has been undertaken by the senior author of this chapter to specify more exactly the genetic basis of susceptibility to early environmental manipulations. Preliminary results indicate that it is indeed possible to select lines strongly or weakly buffered against the effects of stimulation in infancy.

This brief sketch hardly does justice to the large body of literature relevant to the problem under discussion. For more detailed exposition the reader is referred to Chapter 2 of this book. All we wish to establish here is that genetic factors play a most important part in determining the magnitude and direction of the effects of early experience.

THEORETICAL MODELS OF EARLY EXPERIENCE EFFECTS

As we have already emphasized, there has been a marked poverty of theoretical treatment of early experience effects. Attempts

that have been made have either been too broad to have real predictive power, or else they have been pitched to a level dealing with only particular sectors of the problem. We have suggested that two critical problems are involved: (1) the specification of those mechanisms by which the residues of an early experience may be stored, that is, mode of acquisition as a function of age, and (2) the specification of those properties of young systems that may affect long-term retention of any changes that are induced, that is, long-term memory as a function of age. We may deal with these questions in terms of physiological or behavioral categories.

Many of the theoretical positions attempting to deal with the first question have been descriptive in the sense that they have specified periods critical for certain types of storage on the basis of direct (or indirect) data rather than on the basis of any postulated developmental properties. Most psychoanalytic theories on early experience effects belong to this category in that they hypothesize the serial appearance of different "stages" during which environmental events imposed on the organism may be expected to have certain specific outcomes. Thus during the oral stage, matters pertaining to the mouth, the ingestion of food, or biting, have a special importance for determining certain aspects of personality. The ages at which these stages are located can only be loosely specified and, indeed, their occurrence and nature are based only on casual kinds of empirical data. Nevertheless, they accord generally with common sense and have apparently proved useful within the framework of practical psychoanalytic treatment. Within the framework of science, they must be regarded as having uncertain status, but the general underlying idea behind them—the proposition that the organism is constituted differently at different ages and therefore susceptible to certain kinds of influence and not others—is an entirely credible one.

This notion has, of course, had wide favor in the literature dealing with development in animals. Its most popular application has been in connection with the age at which social attachments are just made—in particular, in the matter of imprinting in avian species. As we have indicated, Lorenz (1935) conceived of a very brief period—perhaps a few hours

duration in ducks, geese, and chicks—during which a very rapid, one-trial learning occurred, this having irreversible consequences. However, neither Lorenz nor other workers of similar persuasion have stated why this type of learning is most salient at this time as opposed to other ages, or why it should have such permanent effects. The implication has been that (1) before this time neither the motor nor sensory system is mature enough to allow retention of such information and (2) events occurring first will exert a much greater influence than events occurring later—a primacy hypothesis. The first of these ideas has been stated formally by Hess (1959) in a model which we have already discussed. Whatever its empirical validity—and it does appear to have some—his model has considerable merit in that it makes an explicit attempt to go beyond a simple descriptive definition of the sensitive period and, instead, to specify those developmental variables that should make a certain age critical for certain types of storage.

Another worker who has attempted to search for mechanisms underlying so-called initial periods has been Margaret Vince (1959, 1960). From her studies of learning in juveniles of several species, she has obtained data suggesting that young birds are more highly motivated in the sense that they respond with more vigor both to familiar and slightly unfamiliar objects. However, they show less ability to inhibit responses which are not rewarded. Vince interpreted this to mean that "internal inhibition," in the Pavlovian use of the term, becomes more "stable" with age up to a point, beyond which it starts to decline again. A summary of her results is presented in Fig. 14. Admittedly, these data are difficult to interpret, but they do suggest that a research focus on inhibitory processes may contribute much to our understanding of critical periods in development.

Extensive use of the critical period concept has been made by Scott and his co-workers at Jackson Laboratory, Bar Harbor. The stages of development as he has outlined them for dogs are summarized in Table 4 (Scott, 1962) together with those deduced by Nice (1943) for the song sparrow. It should be emphasized that both these schemes are based not on any theoretical notions about the nature of development, but rather on em-

Fig 14 Positive responsiveness and internal inhibition in some avian species as a function of age (Vince, 1960)

perimental data, particularly those relating to socialization. We have already discussed a sample of the extensive work done on this problem by Scott and his colleagues.

We should note, at this point, that not all workers have found the critical period concept to be useful in dealing with early experience effects. Schneirla and Rosenblatt (1963), in particular, have felt that its acceptance implies a nativism not in line with the

facts about development. Their work on kitten behavior has suggested that the emergence of various patterns of behavior at certain ages depends not only on maturational factors but also strongly on factors of learning and experience that have gone on before—particularly those occurring as a result of highly standardized situations, for example, the female litter situation. Thus the apparent fixity of developmental sequences is derivable from

Table 4 Periods of Development for the Dog and the Song Sparrow

Puppy			Song Sparrow		
Name of Period	Length of Period (weeks)	Initial Event	Name of Period	Length of Period (days)	Initial Event
I. Neonatal	0-2	Birth, nursing	Stage 1 (nestling)	0-4	Hatching, gaping
II. Transition	2-3	Eyes open	Stage 2	5-6	Eyes open
III. Socialization	3-10	Startle to sound	Stage 3	7-9	Cowering—first fear reactions
			Stage 4 (fledgling)	10-16	Leaving nest—first flight
			Stage 5	17-28	Full flight
IV. Juvenile	10-	Final weaning	Stage 6 (juvenile)	29-	Independent feeding

both environmental and genetic factors working together rather than from genetic factors alone. This point of view, as Scott (1963) has pointed out, is not by any means completely antithetical to the critical period notion. Nonetheless, its emphasis on the importance of learning is certainly a useful one.

Another theory we have previously mentioned dealing with formation of early social attachments but not involving the idea of critical periods has been presented by Cairns (1966b). This is directed mainly to explaining the data on lower mammals but presumably has applicability to human infants as well. Starting from an Estes-type of position, the theory proposes that any object or class of objects that appears frequently in combination with other environmental or organismal events comes to have importance in maintaining a variety of maintenance behaviors such as ingesting and sleeping. The presence of the object then comes to be necessary for the stability of such response systems; its absence produces disruption of such responses. The greater probability of animate rather than inanimate objects figuring in such "attachments" is attributed to their greater salience and attention-getting characteristics. As Cairns suggests, the methodology implied by the model involves detailed analysis of the reciprocal behaviors involved in social attachments and focusing on approach and withdrawal responses rather than on general state variables such as emotionality and temperament. Cairns has initiated a program of work along these lines and deals in two papers (Cairns and Johnson, 1965; Cairns, 1966a) with the consequences of social attachment formation within and between species (lambs and dogs).

Two other models dealing with the effects of early experience have slightly different orientations. Brookshue, Littman, and Stewart (1961), on the basis of a study on the effects of early trauma in rats, have put forward a three-factor theory according to which an early experience may have three kinds of residual: a "pure-shock effect," acquired fear, and "instrumental-habit." Presumably the salience of each of these in determining of the type outcome of a trauma will depend on the age at which the trauma occurs. However, the authors did not concern themselves directly with any relevant dimensions of development,

and hence were not able to relate their three types of residual to any particular critical ages. In spite of this lack, the model is an interesting one and has considerable heuristic value.

Denenberg (1964) has formulated a model specifically to deal with the quantitative relation between amount of early stimulation and ensuing changes in emotionality. He has postulated, first, a monotonic relation between the two variables such that the greater the degree of stimulation, the *less* emotional the animal. Such a proposition initially appears to contradict the large amount of data showing bidirectional changes in treated animals. Denenberg has explained these by reference to the Yerkes-Dodson effect, suggesting that performance on a task will be a function of level of motivation (or emotionality) and degree of task complexity. The situation is diagrammed in Fig. 15. What it means, essentially, is that depending on the nature of the task, a certain range of early stimulation can produce increasing or decreasing linear or bidirectional effects. Such a conclusion certainly makes a good deal of sense. However, the logic of the initial postulate seems questionable. It makes little sense to suppose that severe traumatic shock imposed on a very young animal is going to result in extreme docility. In fact, almost the opposite point of view has been considered quite plausible by Salama and Hunt (1964). The matter probably will only be settled when those theorizing about the relation in question can agree on adequate operational definition of the variables involved.

Fig. 15 Theoretical relationship between adult performance and level of emotionality for tasks of varying degrees of difficulty (Denenberg, 1964)

Fig 16 (a) Input and output differentiation as a function of age (b) Storage mechanisms salient at different ages, as predicted from a (Thompson, 1966)

The next schema to be considered is one that has been proposed by Thompson (1966, 1968). Its starting point is the developmental dimension of differentiation. This is considered to increase with age both on the input or sensory and output or motor sides, but it increases more rapidly in the case of the former, as schematized in Fig 16. Thus an organism, as it gets older, becomes capable of making finer and finer discriminations and also becomes capable of making more precise and articulated responses to these discriminanda. Now learning or storage may be regarded as an association made between an input and an output, that is, an S-R bond. Consequently, the model states that some kinds of learning will be more probable at certain ages than at others. At a very young age, it will be undifferentiated input-undifferentiated output, at a somewhat later age, differentiated input-

undifferentiated output, and still later, differentiated input-differentiated output. These three types of storage are considered to correspond, respectively, to habituation-sensitization, classical or emotional conditioning, and instrumental or operant learning. It will be noted also that these categories are very similar to those suggested by Brookshue et al (1961) referred to previously. However, they are derived directly from an application of a developmental dimension rather than a priori or empirically and could have been specified without the aid of any of the nomenclature of learning theory.

The author has further suggested that there must then exist three major developmental periods of age-zones, during each of which any given experience will have certain special outcomes according to the learning involved. These age-zones are described as follows:

- 1 The "temperament adaptation zone." During this time the organism, through the processes of habituation and sensitization, learns a characteristic level and range of responsiveness—not to any particular cues, but to the environment in general. Hence the category "temperament" seems most able to encompass the kinds of behavioral effects produced.

- 2 The "affective-meaning zone." Since input is relatively differentiated at this time (by definition), the organism can learn to respond to cues—but only in an undifferentiated manner. Storage that occurs under these conditions would seem to relate most closely to classical or emotional conditioning—that is, the attachment of emotional responses, positive or negative, to specific cues or cue categories. This period should be characterized by the formation of social attachments, of likes, dislikes, and so forth.

- 3 The "instrumental-meaning zone." During the third age zone, response differentiation becomes relatively high, thus resulting in the domination of storage by means of instrumental learning. The young organism no longer merely reacts to the world passively but can now commence to cope with it by means of specific, well coordinated acts.

These three stages or age zones may relate to age in a somewhat variable manner, depending on environmental factors and also on the genotype of the species involved. How-

ever, if the postulates concerning differentiation and its relation and development are correct, their order of occurrence should be invariant. The approach is thus epigenetic in the sense that the influences of both environment and motivational factors are recognized.

This model and the others we have considered, however, provide little information concerning the importance of early environmental events. It seems commonsensible, as we have already suggested, to suppose that young organisms are in some sense more plastic and therefore register the contingencies of environment with more permanence than do older animals. However, it must also be recognized that notions like plasticity, lability and the like are not only vague in character but also double-edged in the sense that they imply not only ease of entry of information but also perhaps the equal ease of loss of it. The senior author has hypothesized that, whatever the empirical data may finally show, the developmental dimension of growth is probably relevant to the problem under consideration. Growth was defined earlier in terms of increments in the quantity of the system or of the subsystems that make it up that occur directly as a function of age. Such increments may be taken to represent an increasing redundancy, which might be expected to affect the buffering characteristics of an organism. We might expect that a less redundant (and hence less well buffered) system would be more sensitive to the impact of some environmental event than one more strongly buffered, that is to say, it would be more strongly and permanently changed by any given early experience. However, whether any differences should imply more permanence of effects on the part of the less buffered cannot easily be decided by logical analysis. The important collection of essays edited by Wolstenholme and O'Connor (1961) deals directly with this problem, but the data cited by the various authors of those essays fail to yield any very clear-cut solution.

Granting, however, that such concepts as plasticity, lability, and buffering may have some value in formulating broad hypotheses concerning the importance of early experiences, we must recognize that it is also possible to deal with the same problem in a more economical manner without involving any special properties that may accrue to young

as opposed to more mature systems. Development is probably stochastic in the broad sense that the effect of any event occurring at a certain moment is influenced by whatever preceded it in time, either immediately or remotely. This should mean that any changes exerted on an organism very early in its life, provided they are retained for at least a short time, should have a disproportionately large influence than events occurring at an older age. To give a simple example, a parent may designate his child who accidentally knocks over a glass of milk as "clumsy." This may set up in the child's mind an initial acceptance of the attribution of the trait to himself, which makes more likely the acceptance of it whenever a comparable situation again arises.

The most explicit statement of this kind of hypothesis has been made by Campbell and Jaynes (1966) in their "*reinstatement*" theory. The model starts from the findings of Campbell and others showing that the long-term retention of conditioned avoidance responses is, if anything, less stable in weanling as compared with adult rats (see Campbell, 1967). If we accept this conclusion that the isolated memory trace is so impermanent in young organisms, then we must account in some other way for the commonsense-based "fact" that early experience is important. The reinstatement notion attempts to do this by appealing essentially to the stochastic nature of development to which we have already referred. Thus it postulates that any given experience in early life will be retained provided only that it is reinstated in a minimal way at intervals. In this manner, it can be maintained at full strength for an indefinite time. Campbell and Jaynes (1966) present data purporting to show this. They compared memory of a conditioned avoidance response in three groups of animals. One group received at 25 days of age an initial trauma consisting of a number of shocks in a black box, plus three further reinstatement exposures to the situation, a second received the original trauma only, and a third received only the reinstatement trials. All groups were tested for avoidance of the black side in a black-white choice box. The first group showed, over a 30-min trial, significantly greater avoidance of the relevant cue. This rather neat experiment nevertheless has a number of flaws. (1) It

did not involve any adult control groups, (2) the response involved was a relatively complex one, possibly involving a number of components perhaps differentially susceptible to early manipulation, (3) the first group received more training trials than the other two groups, regardless of how these were spread out in time. In view of these difficulties the paradigm study cannot be regarded as having supplied a very firm basis for the reinstatement model. At the same time, both the general ideas put forward by Campbell and Jaynes and their mode of empirical attack are exceedingly interesting and certainly deserve to be followed up.

Very few attempts have been made to formulate precise physiological theories about the effects of early experience. Bovard (1958) suggested that early stimulation acts as a stressor, having the effect of reducing pituitary-adrenal and sympathetico-adrenal medulla responsiveness to later stress. More centrally, the amygdaloid complex and the hypothalamus would also be involved. Such a notion has received support especially from the work of Levine (1961) and makes a good deal of intuitive sense. At the same time, it is very programmatic in scope and hardly suggests specific hypotheses that can be precisely tested.

The theories we have just discussed are broad enough to encompass both human and animal data, although we have focused mainly on the latter. Points of view geared specifically to human young, apart from those emerging from the psychoanalytic framework, are few and far between. Several have been mentioned in the sections on studies of children. Bowlby (1957, 1958) presented a theory to account specifically for mother-child attachments and the effects of disturbing these by separation. His model combines a psychoanalytic and an ethological approach. Specifically, he suggested that the close relation between mother and child emerges out of a number of unlearned behaviors—sucking, clinging, and following—each of which matures at different times during development. Some acts such as crying and smiling on the part of the baby activate or release various maternal behaviors. Such a point of view has considerable value in its emphasis on biologically based variables important to social relationships in human beings.

A second suggestion we consider to be useful was that made by Casler (1961) in his review of the literature on early experience. He pointed out that almost all studies done on this problem have confounded two kinds of variables. These are perceptual or sensory deprivation and maternal deprivation. The first relates to insufficient amounts or variety of inputs, the second, on the other hand, covers the breaking of an already formed attachment between a mother and a child with all the affective consequences that this implies. Thompson (1958, 1960) and Schaffer (1958) have also made this kind of distinction, as noted by Casler (1961). Further, Schaffer has suggested that perceptual deprivation probably has effects up to about 7 months of age, whereas maternal deprivation comes to be important some time after this age. He and Callender (1959), on the basis of data gathered on 76 infants hospitalized between 3 and 51 weeks, were able to elude two major types of syndromes. One of these was "global" in nature and was characterized by an "unfocused inspection of surroundings." The other, which they called "overdependent," involved strong tendencies to demand maternal attention. The first was associated with hospitalization during the first half-year, the second with hospitalization occurring after this age. The refinement of these notions suggested by Schaffer and Emerson (1964) has already been discussed and need not be reviewed here in detail. It should be noted that these authors use the "stage" concept, their formulation being based essentially on the increasing capacity of an infant to discriminate objects—animate and inanimate—in his environment. They do not deal very clearly, however, as Cairns has tried to do, with the reasons why actual social attachments come about, as distinct from specifying with what objects—animate and inanimate—in his end deal explicitly with the importance of early social relations as possibly providing "rules" for later behavior.

The preceding survey of theoretical developments concerning the early experience problem indicates fairly clearly that work in this area has been heavily oriented toward the amassing of empirical data. Even those models that are available are very programmatic in style and provide only broad guidelines for researchers. There are signs, however, that

theorizing is on the increase, and before long the major issues will come to be more sharply defined than they have been up to now

Conclusions

This chapter has attempted to review the salient lines of empirical and theoretical work done on the problem of early experience. It is clear that the area involves a number of quite diverse convergent traditions out of which have come a large volume of studies but little in the way of primary models that can effectively order the data available or supply to the field the kind of unity and theoretical integrity it needs. The chief reason for this appears to be that too little attention has been paid to analysis and definition of the nature of the basic dimension involved—development. We have pointed out, in agreement with Zigler (1963) and Wohlwill (1964), that age is not an experimentally manipulable variable and, in itself, is empty of any real psychological meaning. It is, however, a variable that is correlated with many other changes which do directly affect behavior. These include both genetics and environmental factors working in conjunction. Together they constitute what we ordinarily mean by the term development, and the passage of time, represented by age, gives them a chance to operate in psychologically significant ways. Thus the expression of certain genes may be so timed that certain types of behavior and certain capacities for discrimination and for articulated response will emerge at particular times. Similarly, between one age and a subsequent one, various environmental events may produce either regularities or irregularities in behavior. Thus a rat at the age of, say, 90 days, may be expected to respond in certain ways to an open-field situation not only because of the maturational processes that have gone on up to that age but also because it has been reared in a cage, exposed to a certain light-dark cycle, fed certain food, and so forth.

It is true that these two sets of variables are very difficult to unconfound and also very difficult to manipulate in the first instance. Certainly, we can vary environmental treatment given to some subjects but we can not do this without altering the rate of various developmental processes. Nor can we vary

duration of a treatment independently of the maturational processes that have also been going on.

As a consequence, the study of development involves special problems that need not trouble much of the rest of experimental psychology, dealing as it does with short-term effects of different manipulable variables on adult behavior. As Wohlwill (1964) has pointed out in an incisive review of the problem, many psychologists have felt that the study of development cannot really be regarded as a *primary* field in the same sense that such areas as learning or perception can be. Admittedly, it will be difficult if not impossible to disentangle maturational from environmental variables. Yet this does not mean that regularities in development cannot be found, and we do not have to be committed to a preformist position to suppose that they can (Wohlwill, 1964). Indeed, the work of Schneirla and his colleagues on cats and kittens (Schneirla et al., 1963), focusing as it does on uniformities produced both by genetic and environmental factors in interaction, represents a good case in point.

At the same time, it is clearly necessary that the concept of development be explicated considerably further. We have suggested the kinds of dimension that it must involve, for example, differentiation, growth, and organization. These have so far not had great heuristic value, but this is not to say they might not have were they analyzed in a careful operational manner. It will be particularly desirable to find for them meanings that are more than merely descriptive but are compatible with a genuine experimental framework. The attempt made by the senior author (Thompson, 1966) to distinguish input from output differentiation represents perhaps a step in this direction, since it does give to the term an S-R orientation. How empirically useful this will turn out to be remains to be seen.

Our review of the work done on early experience, both on the level of humans and on lower animals, indicates clearly that the problem is a very viable one, but equally it shows the strong need for more theorizing and a closer liaison between what we have designated as the normative-descriptive and experimental-predictive orientations. Thus while it may be obvious from the large number of studies carried out that early experience is

important, it is less obvious how or why this should be so. To comprehend this broad statement in more precise and articulated terms, we will have to understand more thoroughly just what early experience is and what we imply by the term important. This task will, in turn, require theorizing of the kind already suggested.

On the whole, the animal and human data fit well together. Indeed, we might say that their compatibility is greater than it is in most fields, perhaps because the divergence between man and lower species is least during the earliest stages of development. The constructs needed to describe processes of verbal learning and memory storage are very different from those used to describe classical conditioning in a dog. But those needed to describe those psychological functions appearing in a human infant may also prove to be useful for dealing with the behavior of a newborn kitten or even a rat.

The various theoretical models we have reviewed, though they can hardly match in sophistication and power those elaborated in some other areas of psychology, do suggest that this may be so. Consequently, we may well have, in the area of early experience work, a unique opportunity to provide some very basic principles that will exert a unifying effect on many disparate sectors of the whole field of psychology—between the normative and experimental orientation, between human and animal studies, between a hereditarian as against environmental orientation, and between clinically oriented and general psychology. The fact of development is a fundamental feature of all *living* forms of life. From the simplest plant form to man, all of them have a starting point, grow up, and, in some sense, die. Attention to this basic commonality can be expected to provide rich dividends for the progress of psychology as a whole.

PART III

COGNITIVE DEVELOPMENT

8. *The Learning Theory Tradition and Child Psychology*

SHELDON H. WHITE

" So, when on one side you hoist in Locke's head, you go over that way, but now, on the other side, hoist in Kant's and you come back again, but in very poor plight. Thus, some minds for ever keep trimming boat. Oh, ye foolish! Throw all these thunderheads overboard, and then you will float light and right."

Moby Dick, HERMAN MELVILLE

"Every psychological explanation comes sooner or later to lean either on biology or on logic (or on sociology, but this in turn leads to the same alternatives)."

The Psychology of Intelligence, JEAN PIAGET

The most significant programmatic approach of American psychology, the stimulus-response tradition, still remains an identifiable approach among psychologists who study children. Among child psychologists, as among psychologists in general, it is a waning tradition, we are in the midst of what Hebb (1960) has described as the second American revolution. The first American revolution overthrew introspection, the Psychology of Consciousness, and Titchenerian structuralism, it established stimulus-response analysis, the Psychology of Behavior, and the learning theories. It took a long time to happen. We sometimes describe Watson's 1913 paper, "Psychology as the Behaviorist Views It," as both the opening gun and the decisive ideological stroke of the revolution, but it seems more reasonable to view the changeover as something that took an academic generation to complete itself.

For American psychologists, the case for behaviorism must have been an argument-in-being as early as Dewey's attack on the reflex arc in 1896, the case for Structuralism must have been an argument-in-being as late as

1933, when Boring published his *Physical Dimensions of Consciousness*. Perhaps the slow entry of behaviorism required a period during which young blood gradually supplanted an older generation. Perhaps there was a little more to the slowness than that. At this distance, it seems clear that the turn to a stimulus-response psychology was not as revolutionary as it seemed and that it basically was a reissuing of Psychology's traditional interest in central processes on a new scientific platform. A new platform seemed necessary at the turn of the century because the then-traditional program of Psychology had been built to accept introspective analyses of consciousness, and this platform could not accommodate data not cast in the form of decompositions of conscious material. Thorndike and Pavlov on comparative psychology, Freud on abnormal psychology, Hall on child study, Binet on psychometrics.

It took time for the right compromise to be worked out. It took time to try to consider the possibility of a psychology of animal consciousness (Washburn, 1908; Judd, 1910), for Thorndike (1913) to reject the hypothesis of

ideomotor action, and, finally, for Tolman (1922a, 1922b, 1923, 1925, 1926, 1927, 1932) to develop a series of translations and, ultimately, "operational definitions" to persuade many that the interests of a mentalistic psychology could be located, and worked with, in the behavior of a laboratory rat.

If one may judge by the course of the first revolution, the second will take time. We seem right now to be working toward a kind of cognitive functionalism based on a progressive alignment of the guesswork of psychology and neuropsychology. Function words—"short-term memory," "arousal," "concrete operations," "pleasure centers," "analysis-by-synthesis," "feature detectors," "mediation," "orienting-exploratory behavior"—are proposed on the one side from behavior analysis and on the other from neuropsychological analysis, with each side trying to come to terms with the function that the other proposes. These functions are then arranged into schemes which are speculative models of central processing mechanisms. There is a frank interest in hypothetical constructs, in the conceptual nervous system, and in thinking. (The issue and reissue of books about thinking shows such an increase in operant rate as to suggest that someone, somewhere, is reinforcing the word—*Thinking* by Bartlett [1962] and *Thinking* by Humphrey [1963], *The Psychology of Thinking* by Vinacke [1952], *Thought and Language* by Vygotsky [1962], *A Study of Thinking* by Bruner, Goodnow, and Austin [1962], *Thinking From Association to Gestalt* by Mandler and Mandler [1964], *Modes of Thinking in Young Children* by Wallach and Kogan [1965].)

The learning theory tradition brings into child psychology emphases which are not constant but which show some of the effects of this evolutionary process. After all, a good part of the revolution was generated out of the tradition itself. As Hunt noted a few years ago:

It can be said that stimulus-response methodology has been undoing stimulus-response theory. Or, at any rate, stimulus-response method has produced evidence that has demanded so much revision in stimulus-response theory that the new theory has few resemblances to the one which originally went by that name. (Hunt, 1961, p. 8)

Although the learning theory tradition is still a viable intellectual force among psychologists, still discussed and taught to students, there has been a significant alteration in the pattern of research activities built upon it. Papers devoted to basic research, or to development or analysis of the learning theories, have shown a marked decline—a comparison of the journals of today with those of a decade ago will show this. At the same time, the stimulus-response tradition shows an intensification of effort in what were once its fringe areas—analysis of social and clinical psychological phenomena, behavior therapy, and behavior engineering. It is this changing pattern of stimulus-response studies, a body of research activity floating free of its theoretical core, which has in recent years come to impinge upon child psychology.

Other approaches to child psychology, with which the tradition is necessarily in interaction, are themselves changed from what they were. Under the sway of one of the strongest of the revolutionary forces, Piaget, they have become significantly more ideological—receptive not only to Piaget, but to Werner, to the psycholinguistics-cum-nativism inspired by Chomsky, to ethology, and to the Russian scheme. It is not true today, as it once seemed to be, that the S-R psychologists alone offered an organized theoretical program to a body of child psychologists largely interested in norms rather than theory, largely interested in the issues of social adjustment rather than the issues of psychological analysis. Within child psychology, the confrontation is now with alternative and seemingly worthwhile conceptions of theory, of usable data, and of the learning and problem-solving processes themselves.

We are not concerned here to discuss the learning theories themselves. Most psychologists know something about them; they have been summarized well elsewhere (Hilgard and Bower, 1966; Koch, 1959); they are not germane to child psychology, strictly speaking. The learning theories were not designed to accommodate the data of children's learning, and it is only by making some assumptions that one can connect them to such data in a general sort of way. What has been brought to child psychology is a surrounding pattern of analyses, an understructure and a superstructure. The understructure, or pretheory, seems

most clearly visible in historical examination. The superstructure is made up of a set of speculative analyses, or interventive programs, which carries the S-R approach to topics in cognition, social and clinical psychology, education, psychotherapy, or applied psychology. To encompass these, our discussion will sample the range of such activities being undertaken with children today.

Prominent among the sources of the American S-R tradition was the work of Ivan Pavlov. From the early decades of this century until quite recently, the American behavioristic tradition and Russian reflexology coexisted apart from one another—both descendants of Pavlov, but each working through the issues posed by Pavlov in diverging ways. About a decade ago, American psychologists reestablished contact with the Russian work, at first through some significant secondary sources (Razran, 1961, Berlyne, 1960) and then through translations and more extended reviews (e.g., Luria, 1960, 1961, 1966a, 1966b, 1968, Sokolov, 1963, Vygotsky, 1962, Zeigarnik, 1965, Uznadze, 1966, Pevzner, 1961, Konoiski, 1967, Bernstein, 1967, O'Connor, 1961, Lynn, 1966).

While Soviet psychology has not developed the range of activities characteristic of American psychology—because, for one thing, the Russians subdivide psychological research differently among the specialties of physiology, psychology, and pedagogy (Brackbill, 1960)—it has developed an interestingly divergent set of analyses of the problems of learning and adaptation toward which both Russians and Americans were pointed by Pavlov. More neurological than the American S-R approach, Russian reflexology has kept alive an interplay between neurophysiology and psychology. Where the Americans have placed intervening variables between the stimulus and the response, the Russians have placed hypothetical constructs. This does make a difference in practice, in spite of in-principle arguments to the contrary. The Americans begin things with stimuli, hypothetical start buttons which defy exact empirical definition. The Russians, aware that there is as much efference as afference to the intake of experience, have been concerned to analyze out mechanisms—the orienting reflex, orienting-investigatory behavior—which are likely to be important factors in the definition

of the stimulus. The Americans have populated the innards of the organism with logocisms, if-then wiring which sometimes proliferates into complex skeins of logical or mathematical central hypotheses (e.g., Berlyne, 1965). The Russian conceptions of central processing have employed more complex physicalistic metaphors, which often are fragmentary and vague. These divergences in the Russian and American S-R traditions have led to significantly different approaches to learning and cognitive development. Today, certain contrasts between Russian work and American work seem to suggest some of the less obvious assumptions and goals built into the learning theory tradition. We will later be concerned with such contrasts.

BEHAVIORISM AND GENETIC PSYCHOLOGY: THE FIRST CONFRONTATION

It seems worthwhile to begin by asking why the stimulus-response tradition came so late to child psychology. S-R analyses of children's behavior did not become really prominent or widespread in American psychology until the middle 1950s. Yet, for several decades before this, the learning theories had been overwhelmingly in the center of theoretical efforts in psychology, coexisting with a sizable establishment of child psychologists who took no substantial guidance from them.

The anomaly is a little more surprising because John B. Watson had specifically made child psychology the intended center of his behavioristic reform. In 1917, Watson was awarded \$100 by the Committee on Grants for Research of the American Association for the Advancement of Science to allow him to study the development of reflexes and instincts in infants. This was eight years after the first American description of Pavlov's work (Yerkes and Morgulis, 1909), four years after the declaration of Behaviorism (Watson, 1913), four years after Hunter's important comparisons of animals and infants (Hunter, 1913), and coincident with the first American research on conditioning—significantly, research employing children as subjects (Matteer, 1918). Watson did establish an infant laboratory and it bore fruit in some of the well-remembered documents of the Behaviorist era. Watson's analysis of the emotions

(Watson, 1919), his conditioning of Albert (Watson and Rayner, 1920), and his sponsorship of an environmentalism based on conditioned reflexes (Watson, 1926). But the infant work helped to promote a revolution in psychology at large while having curiously little lasting influence upon those psychologists who studied children.

In a recent volume, Kuo (1967), one of the earliest and most active behaviorists, regards this as a historical misfire.

In reviewing the history of the behavioristic movement one most important aspect has long been overlooked: the ontogenetic implications. These were clear to me in the basic tenets of behaviorism, in Watson's own later interest in the behavior of human neonates, in the vigorous anti-instinct campaign in the 1920's, and in Watson's effort to catch up with the anti-instinct trend. An objective and unbiased historian of science should have been able in the late 1920's to forecast the future trend of development of the original Watsonian behaviorism, namely, the ontogenetic approach to the study of animal behavior. The studies of various aspects of the ontogeny of postnatal behavior after World War II must be regarded as a continuation of the 1930's trend and partly as a silent (in most cases) protest against the rat-learning psychologists from Tolman to Hull, Skinner, and their followers, who seem to have deviated from the original tenets of Watsonian behaviorism (Kuo, 1967, p. 10).

In this quotation, Kuo seems to underestimate the persistent drive of Watson (and Tolman and Hull and Skinner) to use animal studies as a vehicle for the indirect study of human behavior. Watson's own motives for the study of infant behavior were clear; he saw in such studies a vehicle for the reform of society.

The behaviorist has an axe to grind, you say, by being so emphatic? Yes, he has—he would like to see the presuppositions and assumptions that are blocking us in our efforts to spend millions of dollars and years of patient research on infant psychology removed because then, and only then, can we build up a real psychology of mankind (Watson, 1926, p. 11).

Behaviorism ought to be a science that prepares men and women for understanding the principles of their own behavior. It ought to make men and women eager to rearrange their own lives, and especially eager to prepare themselves to bring up their own children in a healthy way. I wish I could picture for you what a rich and wonderful individual we should make of every healthy child if only we could let it shape itself properly and then provide for it a universe in which it could exercise that organization—a universe unshackled by legendary folk-lore of happenings thousands of years ago, unhampered by disgraceful political history, free of foolish customs and conventions which have no significance in themselves, yet which hem the individual in like taut steel bands. I am not asking for revolution, I am not asking people to go out to some God-forsaken place, form a colony, go naked and live a communal life, nor am I asking for a change to a diet of roots and herbs. I am not asking for "free love." I am trying to dangle a stimulus in front of you, a verbal stimulus which, if acted upon, will gradually change this universe. For the universe will change if you bring up your children, not in the freedom of the libertine, but in behavioristic freedom—a freedom which we cannot even picture in words, so little do we know of it. Will not these children, in turn, with their better ways of living and thinking, replace us as society and in turn bring up their children in a still more scientific way, until the world becomes a place fit for human habitation? (Watson, 1930, pp. 303-304)

One wishes that Watson's faith in Behaviorism might have worked out. Watson's utopian behaviorism finds echoes in Skinner's writings in our own day, but it was not the promise of social reform that initially won psychologists to the behavioristic cause. Most psychologists seem to have bought a methodological behaviorism stripped of the extremes of peripheralism, environmentalism, and utopianism espoused by Watson. Probably they bought it because it was crystallized into workable programs of scientific research and development by the various learning theorists, principally Tolman, Hull, and Skinner.

The Impact of the Learning Theories

The learning-theory movement was a complex and many-faceted social movement within Psychology. As is the case with any social movement, different individuals probably went along with it with a variety of understandings, purposes, and configurations of consent. What was the broadest basis of consent, the least disputed understanding and agreement among the users of the learning theories? It seems likely that most people went along with the learning theories because, first, they offered a peremptory though plausible solution to certain epistemological, metatheoretical issues that were a plague and a puzzle to psychologists at the turn of the century and, second, because they presented a well-reasoned plan for cooperative research to psychologists concerned to establish for their field a mutual, cumulative, scientific effort.

Epistemology and Metatheory At the turn of the century, psychological writing was almost buried in discussion. Anyone disheartened by the routine "stamp collecting" research often found in current psychological journals should read the *Psychological Reviews* of the opening decades of this century to get a sense of a different boredom. There is a tortuous obscurity to much of the writing, a ponderousness, as various authorities are compared and reconciled, as tiny psychological issues are sifted for hemidemisemiquavers of implication, as author after author weighs in with his own elaborate statement of position on the mind-body problem. In the midst of this sea of dialogue, the modern reader can almost feel the relief as a modern piece of stamp collecting comes along—a close, careful naturalistic observation of animals (Watson, 1908), or an empirical investigation of handwriting analysis (Hull, 1919).

Much of the obsessing was about a circle of interconnected issues having to do with epistemology, the mind-body problem, and the relationship between physics and psychology. There was, on the one hand, a concern that these questions be settled adequately because they were fundamental for Psychology's imitation of empirical inquiry and, on the other hand, an exasperation with all the disputing and a frequently voiced desire, expressed by Titchener no less than Watson,

that the problems of psychology be separated from the problems of philosophy. Behaviorism and, subsequently, the learning theories offered a preemptive way out, and it was taken.

We are generally aware of certain ideological elements which were put together in the construction of the learning theories: Darwinism, Behaviorism, the connectionism of Thorndike, the reflexology of Pavlov, and the logical positivism of the Vienna Circle. These contributed semifinished ingredients to the system builders. One important ingredient, a physicalistic epistemology of "naïve realism," from which standpoint the mind-body issue could be dismissed as a pseudo problem, was a solution to the problems so prominent at that time. Today, living in a different ideological environment, we tend to underestimate the significance of that solution.

Cooperative Program Once it was settled that the psychologist might look easily at a world of objects and movements, there remained questions of how, and for what the examination should be directed. The ingredients of the learning theories, woven into elaborated programs by the system builders, provided a justified agenda. There was a vision of reinforcement as a natural selection process in the environment which could select out adaptive animal behaviors—hence the justification for an intensive examination of learning as a reinforcement process. There were techniques for the study of learning on which the field could to some extent standardize because of the belief that such techniques got close to the basic and universal forms of learning. Finally, there was an understanding of science as a process where empirical laws are collected to be organized into deductive theories, and there was a miscellany of papers designed to show that the S-R scheme under development could, in principle, be brought to a point where it might assimilate subtle or complex forms of human behavior (e.g., Hull, 1930, 1938)—these offered a vision of future significance for series of small-scale studies.

So much controversy of so many sorts has swirled about what learning theories could or could not do, their rightness or wrongness, that it is easy to miss one's way as one tries to discuss their purposes. What seems clear and evidential, above all, is that the learning

theories provided a basis for the creation of a great volume of American research work. Filtering out the enthusiasms, the inadvertences, and the stubbornnesses which carry opponents and proponents of a system to extremes, the learning theory movement has probably not been widely accepted because its adherents have believed that (1) all human beings are "nothing but" simple mechanical contrivances, (2) all human behavior is learned behavior, (3) the stimulus is cause and the response is effect. The theories have had a thrust which leads in those directions, but for every adherent who takes his theory "that far" there are others who do not. However, though individuals have not bought such arguments in principle, the theories have had a *de facto* influence channelling research in selected directions as though such principles were held. A fairly clear case for this can be made with respect to the heredity-environment issue (White, 1968a).

In the view being advanced here, behaviorism and the learning theories won the adherence of many because they found for Psychology a reasonable species of psychological reality, and because they then laid down a paradigm of cooperative research procedure which might search that reality with a hope of significant findings. If one paid the price of the assumptions (thoughtful, intelligent assumptions, articulated by some of the best minds of the field), one could stop the hair-splitting and the throat-clearing and one could move into intensive scientific development. It was not necessary, and it is unlikely, that all who adopted this paradigm were intuitively persuaded by the model of organismic behavior implied within it. There is a statement by David Hume which goes, roughly, "If I had to live by my philosophy I would die within a week." However, the collective wisdom of psychologists in this tradition was inexorably formed by the model, journal articles traded information about S-R regularities, but the myriad of odd phenomena regularly turned up as by-products of S-R analyses—"set" effects, sensitization, habituation, sensory preconditioning, expectancy effects, etc.—were either set aside or else attempts were made to digest them into the S-R scheme.

The Genetic Tradition

We have this strong force in the theoretical psychology of the early decades, specifically aimed toward child study by Watson, and it is difficult to find any clear influence in the child psychology of the era—some enhancement of the study of learning, occasional papers expressing antipathy for the S-R model of man, and sympathy for opposing Gestalt arguments. Others beside Watson brought animal procedures to child psychology without conspicuously attaching theoretical strings (e.g., Weinbridge and Gabel, 1919). The study of children's learning moved off at a modest pace, using techniques borrowed from the Ebbinghaus tradition and from comparative psychology, the learning construed in the less diastic and less committing stimulus-response psychology of Thorndike's *Educational Psychology* (1913-1914), the research material organized—clustered would be a better word—only somewhat around issues of possible educational interest, such as massed versus distributed practice, or whole-part learning. The learning processes were a minor interest in the child psychology of the 1930s and 1940s. The first few volumes of *Child Development* from 1929 on place very little emphasis on learning work, parallel volumes of the *Journal of Genetic Psychology* contain a great deal of animal work but also show a steady, small, miscellaneous stream of papers on children's learning.

Part of this disengagement of child psychologists from the learning theory movement might be attributed to a generally pragmatic and undoctinal style of this group, somewhat isolated from the main body of psychologists and committed more to interdisciplinary explorations. Not only learning theory but also psychoanalysis was not caught up. Systematists more indigenous to child psychology—Hall, Baldwin, Werner, the early Piaget—did not have a strong following. It is common to hear descriptions of the child psychology of the 1930s and 1940s as an enterprise devoted to atheoretical fact-gathering, and there seems to be some truth to that. Probably, the general torpor and dilapidation of research in child psychology so frequently commented upon in the early 1950s—see the *Annual Review* entry on "Developmental Psychology"

by Barker (1951), and then successive years—reflects a kind of entropy of purpose due to this disinclination to articulate theory and program

However, one has the definite feeling that learning theory did not cross over to child psychology in the 1930s and 1940s because of factors more active than the disinclination to theorize. However pragmatic and atheoretical the child psychological literature might have appeared in contrast with other areas of psychology burgeoning with learning theories and personality theories, one did have a group of researchers who were vigorous in generating and trading research information. This implies a shared theory in some sense of the term. Furthermore, the active period of the Child Development Movement in the 1930s coincided with the period when the learning theories were most actively under development in American psychology, when they were most exciting, and when it was most possible to be optimistic about possibilities. This vigorous thrust might, perhaps, have been walled off by theoretical passivity, but it seems more likely that it was checked by the existence of another point of view which was antipathetic to it. There are signs that a belief system with some integrity was maintained among child psychologists without much overt rehearsal. One might have called this belief system the "genetic point of view" at the turn of the century, and today one would be inclined to call it the "comparative-developmental point of view"—giving to Werner, rather than Piaget, the broadest contemporary statement of the position if not the most penetrating use of it.

There is an intricate and interesting history to be traced here, which we shall discuss in outline form. We are interested in why the learning theory tradition did not take root in child psychology in the 1920s and why it did in the 1950s. The argument, so far, is that there existed a not-well-articulated genetic tradition which was vigorous enough to successfully oppose its assumptions in the first half of this century. It is thus possible to look over that half century and argue, looking at the learning theory tradition, that Psychology has been too environmentalistic in its assumptions about human adaptation, or else, looking at the genetic tradition, that Psychology has

been too hereditarian in its assumptions (Hunt, 1961).

The genetic tradition arose from the speculations about human development formulated by the Evolutionists such as Spencer, Darwin, and Galton, and it has had a continuous influence upon American psychologists. For various reasons, the spokesmen who might have been prominent exemplifications of the position were not perfectly reputable in an era when American psychologists were concerned with the clarity and researchability of a theory. There was Hall, who was entirely too poetic and whose Recapitulationism, taken literally, could be disproved by empirical test (Grinder, 1967). There was Freud, who embedded his system in Wagnerian scenarios which almost disguised the fact that his theory of child development was another rendition of the genetic point of view. And, a little later, there was Werner's *Comparative Psychology of Mental Development*, whose influence is now growing but whose system for a long time seemed too loose and too philosophical for wide acceptance.

The transcription of the genetic point of view into a rigorous and tough-minded program for maintaining and containing research, always a central issue for American experimental psychologists, never took place, and has not yet taken place. The dynamics of the position—its view of what forms the child—did dictate that one should be concerned to understand the detailed flow of normative ontogenesis of behavior, and that within that framework one should be concerned about the potential for adjustment.

Certain interesting views of inquiry were opened up by the anthropometry of Galton, the norm-gathering of Binet and Henri in the 1890s, and the questionnaires of G. Stanley Hall. Hall fostered these in the Child Study Movement, and for a time promulgated a covering evolutionary ideology (Hall, 1908), but his system shivered after his death into a few catch-phrases remembered only in textbooks about childhood and adolescence (Grinder, 1967). The approach, if not the words of Hall must have been sustained to some extent in the Child Development Movement, where there are so many similarities. There was the eclecticism, cross-disciplinary but centering in Psychology, there was the de-

votion to broad norm-gathering, there was the orientation to Education, there was a commitment to a geneticism which, faintly but firmly, kept alive the ideas of an innate hierarchy of talent, and the view of human development as a progression through maturational schedules. Terman and Gesell, Hall's students at Clark, were bellwethers in the developmental psychology of the 1930s and 1940s. Terman's interest in genius and stupidity was sustained from his earliest work as a student in Hall's laboratory (Terman, 1906). His work continued a scientific extension of the intermixture of psychometry, anthropometry, and eugenic utopianism which motivated Sir Francis Galton. Gesell maintained interest in psychological embryology, acknowledging Hall's influence and developing what would appear to be the sensible empirical core of his system.

Huxley was right when he insisted that the study of embryology subtends the entire life cycle. The higher as well as lower orders of behavior were built by evolutionary processes, and they survive only through embryological (ontogenetic) processes however much they bear the final impress of acculturation. Learning is essentially growth, and even creative behavior is dependent upon the same kind of neuronic growth which fashions the capacities of the archaic motor system, *in utero* and *ex utero*. The performances of genius belong to a hierarchical continuum because there is only one physiology of development. There is but one embryology of behavior (Gesell, 1952, p. 153).

In brief, the learning theory tradition growing out from Watsonian behaviorism did not win a strong following among child psychologists because of their concern to develop a quite different set of assumptions about children, a genetic tradition, with an integrity of its own and research concerns of its own. In our own day, that genetic tradition has been re-aroused as a force in American child psychology primarily because of the new vigor and incisiveness manifest in Piaget's work and the work of the Russian developmental theorists. Piaget's work is either child psychology or it is an empirical analysis of historic epistemological issues using children. The Russian work is child psy-

chology incidental to, and integrated with, the pursuit of a psychobiology of behavior. One sees that the new geneticism is something more than the reassertion of a maturational, stagelike, recapitulationistic process of growth and one must move outside child psychology to fully understand what it represents.

One cannot fully understand the point of view of genetic psychologists toward children unless one understands something about a great deal of other information not having to do with children which forms the point of view. Indeed, lengthy and detailed observations of children began some years after the point of view was formed at around the time of Darwin. The same might be said of the learning theory point of view: it states what *should* be true of children in consistency with a body of assumptions and data outside child psychology. In this writer's judgment, the conflict between the learning theory tradition and the tradition of genetic psychology was and is another chapter of the ancient and honorable conflict between empiricist and rationalist views of man.

Psychologists have a sense of the historical continuities which has led to a continuous reassertion of an associationistic scheme for psychological affairs, because good histories (Warren, 1921; Boring, 1951) have traced the lineage clearly. We do not have nearly as good a sense of the continuous reassertion of psychological schemes descending from Cartesian rationalism. One suspects a good history of this kind could be written. There is a tradition which has elaborated exactly those elements of Descartes' epistemology which the British empiricists were concerned to expunge: the acceptance of acts of reflection in the psyche, and the attempt to classify them, the acceptance of a priori intuitions in the mind, the concern to align brain and mind, and, finally, the assertion of discontinuities between lower-order and higher-order mental processes, the argument that they differ qualitatively rather than quantitatively. This is a characterization of Descartes' psychology, but it is also a description of the psychology of Piaget.

Evolutionism, and the various theories of human mental functioning which flowed from it, added a genetic wing to the rationalist scheme of things. That new genetic psychology seems to have begun with Herbert

Spencer, whose philosophical influence was extended toward Piaget via Bergson, toward neurology and psychiatry via Hughlings Jackson, and toward the American genetic tradition via G. Stanley Hall. The great principle of development which Spencer applied to everything, that all systems progress from "an indefinite, incoherent homogeneity to a definite, coherent heterogeneity," survives today in child psychology as Weiner's orthogenetic law.

In the terms just sketched, one would argue that Watson's behaviorism, and the subsequent elaboration of the learning theories, did not have a significant influence on child psychology in the early decades of this century because child psychologists had a rival theoretical scheme, more or less implicit and unrehearsed, in the genetic-rationalist tradition. Not really well suited to development through research, not persuasively reasserted, this tradition failed to keep things going and the child development movement lost vigor. That which organized and rationalized its research ventures was not rehearsed and adjusted and expanded. Ultimately, the learning theory tradition did infuse a programmatic sector into child psychology—because there was a vacuum?—because of change in the learning theory tradition? What did come into child psychology was a tradition in evolution, the evolution intended to accommodate the S-R analysis to the rationalist and developmental issues.

THE LEARNING THEORY TRADITION TODAY: HOMOGENEITY AND HETEROGENEITY

A significant movement toward stimulus-response analysis did emerge among child psychologists in the mid-1950s, unified in some senses and conglomerate in others. The unity was somewhat submerged in that there was not much theoretical or programmatic writing designed to explain or justify these kinds of efforts. In the mid-1950s, the learning theories, their assumptions, and their various extensions, were so widely understood in the professional culture of American psychologists that such efforts seemed more or less natural. The diversity resulted from the fact that the S-R tradition moved into child psychology embedded in several programmatic

packages. These packages—at least two distinct approaches to the strategy of basic research, at least a half-dozen more S-R approaches to issues other than learning—had, generally speaking, been developed outside child psychology and then diffused into it. Though all of these programs flew the flag of behavior theory or behavior analysis, they were discrete in the sense that a faith in one did not, logically or in fact, imply a faith in the others. Proponents of behavior analysis were divided about whether basic research should proceed by an atheoretical functional analysis or a learning theory approach, and they showed varied patterns of interest in extensions of the S-R scheme to cognitive, social, and clinical phenomena, or to the development of interventive techniques for behavior therapy, behavior engineering, or programmed learning.

This differentiation of approaches has been hardening, and today it would be careless to view all of the proponents of a stimulus-response psychology as interested in learning theory, S-R analysis of human behavior, behavior therapy, etc. There are commonalities, but they are subtle and one must pick and choose one's way carefully to find them; there is probably no completely uncontroversial way to do so.

One thing which unites stimulus-response psychologists is, of course, their commitment to a psychology of *Ss* and *Rs*, and to transactions with observable behavior change. What is often called the "learning theory point of view" would seem to amount to these assumptions:

- 1 The environment may be unambiguously characterized in terms of stimuli.
- 2 Behavior may be unambiguously characterized in terms of responses.
- 3 A class of stimuli exist which, applied contingently and immediately following a response, increase it or decrease it in some measurable fashion. These stimuli may be treated as reinforcers.
- 4 Learning may be completely characterized in terms of various possible couplings among stimuli, responses, and reinforcers.
- 5 Unless there is definite evidence to the contrary, classes of behavior may be assumed to be learned manipulable by the environ-

ment, extinguishable, and trainable (White, 1969)

The first two assumptions have to do with the reality of the psychologist as scientist. Though to many psychologists these seem to be easy and convenient, our glance at history shows that they imply significant commitments. The last three represent a Darwinistic conception of behavior adaptation—the survival of the fittest response through reinforcement—which can be traced back to Thorndike (1913-1914, 1931) and which, with variations, runs through the learning theories.

The learning-theory tradition has characteristically been a rigorous movement, paying great attention to observational proof and parsimony of interpretation. There has been an emphasis on small-scale experiments with tight control of conditions, usually experiments on learning where specifiable changes in conditions produce countable changes in behavior (White, 1963). There has been an emphasis on bringing terminology "close to behavior." Operational definitions are sought for key terms (Spiker and McCandless, 1954); other systematic positions are examined for the possibility of an S-R translation, and in applied work the thrust of the tradition is toward the maximum reduction of problems and goals to observable, countable patterns of behavior (Kiasner and Ullman, 1965). In keeping with this urge to avoid vagueness, this tradition more than any other has brought instrumentation into child psychology to regularize the administration of experimental procedures.

There is, then, a unifying commitment to a scientific universe of Ss and Rs, an understanding of behavioral adaptation as a process of response selection by reinforcement, and a methodological drive toward precision of observation and parsimony of interpretation. With this in mind, we can look at the diversity of expression of the learning theory tradition within child psychology. The literature has encompassed the following:

1 A small literature of operant analysis, with methodology carefully articulated but not oriented to theory, based on the program of B. F. Skinner (1938, 1953). This is largely concerned with the functional analysis of the behavior of the child, with both normal and disturbed patterns of behavior analyzed as

under the control of reinforcement contingencies in the environment (e.g., Bijou and Baer, 1960, 1963, Ferster, 1961).

2 A small body of studies directed at assumptions or variables of concern to the theoretical position of Hull (1943) and Spence (1936, 1956), and in some general sense oriented toward the understanding of construct, law, and theory on which that position rests (e.g., Spiker, 1963, Castaneda and Palermo, 1955, Zeaman and House, 1963).

3 An eclectic group of studies, not identified with any program, yet analyzing procedures of classical conditioning, instrumental learning, verbal learning, and so forth, to look for the sorts of regularities that might usually be caught up in such programs (e.g., Stevenson and Weir, 1959, Weir, 1964, Lipsitt, 1963, 1967, Palermo, 1961, 1962, Brackbill, Fitzgerald, and Lintz, 1967).

4 A ramified set of attempts to translate issues of socialization and social interaction into stimulus-response terms, and to explore such issues experimentally. This includes studies of social reinforcement (Gewirtz and Baer, 1958a, 1958b, Stevenson, 1965, Gewirtz, 1967, Landau and Gewirtz, 1967), studies of imitation and "vicarious reinforcement" (Bandura and Walters, 1963, Bandura, 1965b, Baer and Sherman, 1964) and the analysis of conscience (Aronfreed, 1964).

5 Attempts to enlarge the framework of stimulus-response analysis to encompass verbal behavior (Skinner, 1957), curiosity and exploration (Berlyne, 1960), attention (Zeaman and House, 1963), symbolization (Kendler and Kendler, 1962, Reese, 1962), inference (Kendler and Kendler, 1967), and reasoning and planning (Maltzman, 1955, Staats, 1961, Berlyne, 1965).

6 Finally, a series of practical attempts at education, behavior engineering, and behavior modification, which have in common the attempt to train humans using manipulations of contingent reinforcement schedules. These efforts are manifold and widely directed. One major sector works toward the teaching of the normal child (Lumsdaine and Glaser, 1960, Skinner, 1968) and the other toward special education or behavior therapy (Kiasner and Ullman, 1965, Ullman and Kiasner, 1965, Bijou and Baer, 1967).

It might be said that this list of topics

underestimates the diversity of these efforts. It implies that the S-R tradition has been carried in all these directions without any "bending." It does not convey a proper impression of the huge volume of work fitting under these categories.

In the 15 to 20 years since the learning theory tradition entered child psychology, there has been a continuous acceleration of the volume of published efforts, but at the same time there has been a diminution in the first two categories of effort given above—less laboratory studies of schedules of reinforcement, and less basic research devoted to the development of the Hull-Spence theory. The two significant nuclei, the Hull-Spence learning theory and Skinner's program, still have some direct influence in the way their collaterals are evolving. Those coming from the Hull-Spence tradition have been devoted to continuing theoretical analysis, trying to open up new veins of S-R analysis which might provide theory to account for children's behavior. Those coming from Skinner's orientation have, like him, disregarded theoretical analysis for its own sake and have moved out of the laboratory toward behavioral engineering. Substantially different issues arise in the course of the theoretical thrust and the practical thrust.

THEORY-DIRECTED ANALYSIS

The traditional purpose of the learning theories was to serve as a framework for a cumulative development and integration of research information about learning. To provide the basic research, a family of procedures has been used, descendants of the verbal learning studies of Ebbinghaus and G. E. Muller, the salivary conditioning of Pavlov, and the trial-and-error problems of Thorndike. All these form a family because they have special characteristics in common, differentiating them from other procedures through which one might conceivably make observations or inferences about learning processes. In most of the special procedures, the subject's time to observe or act is parcelled out in trials. The time and place of learning is fixed and the environment is isolated, uninterrupted, and asocial. Discrete cues are made prominent. Criteria, set up by observer or instrument, are enforced so that countable,

timeable, scorable responses are fished from the stream of behavior. The typical research procedures for the study of learning have regularized it, made the learning situation more repeatable across individuals and laboratories. They have emphasized the maximum quantification of antecedents, consequents, and the time course of the process. The theories of learning were based upon the possibilities of controlled variation and experimentation possible when learning had been so regularized. One influence of the learning theory tradition upon child psychology has been, simply, to provide support for the dissemination of such regularized techniques as instruments for basic research into children's learning (Spiker, 1960, White, 1963).

The significance of the fact that such techniques have become conventional should not be underestimated, then almost exclusive use is in itself tantamount to what some might call the adoption of a theory of learning. Using these techniques as a window, one often does not "see" learning when the stimulus conditions are out of the view of the experimenter, when the change in behavior occasioned by learning does not occur fairly promptly, or when the effects of something learned may manifest themselves with equal probability in any of a dozen response indices. One tends to underestimate how much the problem of everyday learning may depend on the noisiness of the unpurified environment (White, 1966a). And, in child psychology, one tends to confuse the learning registered by the instrument with another, unregistered, learning process through which the child is trying to adapt to the instrument (Levin and Hamermesh, 1967). Of course, all this is not to say that experimenters cannot and do not make the effort to see beyond their formal data, or that this tradition alone runs the risk of instrumental nearsightedness. The point being emphasized is that a significant part of the learning theory tradition has been carried into child psychology by the sheer adoption of the specialized observational procedures adapted to that tradition.

If one looks for the programmatic impact of the learning theories upon the study of children's learning one must proceed a little carefully. No learning theory has ever been constructed from studies of children or been specifically directed toward them. Strictly

speaking, there is no learning theory in child psychology. Setting aside direct applicability, there is a way in which the Hull-Spence theory and its collateral have been construed as a potential basis for the understanding of children's learning.

1 One assumes, as Hull and Spence did, that there is an elementary bonding process through which bits of the environment become attached to bits of behavior. One assumes that the universal and elementary basis of all learning is the formation of an S-R bond. This is a behavioristic form of an old neurological suggestion that all organismic adaptation rests on more or less complicated forms of the reflex arc. Hull's systematic contribution (Hull, 1943, 1951) was primarily an attempt at an intensive analysis of the S-R bonding process. His theory provides an intensive analysis of one encounter during which a set of stimulus conditions are an occasion for a response. In this analysis, the stimulus conditions are described as quantified variables and their influence traced schematically to intervening variables, whose influence in turn is traced to response characteristics. The system provides that some of the flow through these lines of influence will influence performance momentarily, while others will make for the lasting influence that we call learning.

2 One assumes that all the more complex kinds of problem-solving are potentially decomposable into sets of interacting S-R bonds. Spence (1936, 1937, 1956) and Hull (1952) attempted a rigorous decomposition of one order of complexity—the situation, in two-choice discrimination learning, where the subject's behavior may be viewed as the resultant of the interaction of two competing S-R links. This analysis has been quite controversial, as well it should be, since it offers a test for the most significant promissory note of this type of theory—that a rigorous way can be found to multiply the one-S-one-R analysis through “composition laws” into a predictive schematic for complicated kinds of learning, conceived as many-S-many-R situations. Other examples of the attempt to provide such composition laws rigorously are Miller's (1959) analysis of conflict and displacement, Spiker's (1963) stimulus interaction hypothesis, and Zeaman and House's

(1963) attentional theory of discrimination learning.

3 All of the worked-out decompositions have been for experimental situations that are limited in complexity, but a large number of other analyses have been offered in which various interesting domains of behavior have been interpreted as S-R systems without much specification of the form of the composition laws which might be predictive for them. This is the speculative superstructure of S-R analysis extending from the learning theory base to the significant targets of psychological analysis. It contains a large literature, of mixed value. The best of this literature consists of carefully worked out treatments of imitation (Miller and Dollard, 1941, Bandura and Walters, 1963), psychopathology and therapy (Dollard and Miller, 1950), frustration-aggression (Dollard et al., 1939), symbolic processes (Mowrer, 1960), and thinking (Berlyne, 1965). In these treatments there is manifestly some effort, not always successful, to keep novel S-R constructions within the epistemological and metatheoretical boundaries within which the terminology was framed. In less useful speculative treatments, the S-R terminology seems to degenerate into a catch-all scientific jargon. On the more careful side we have the laborious and intricate literature which tries to capture a little bit of the activity of representation in an S-R mediation scheme (Kendler and Kendler, 1962, Reese, 1962), on the less careful side we have the practice, common now, of using the term “mediation” as an acceptable way to say “thinking.” Today, too, there are the offerings in educational psychology in which various generalizations are wrenched from their origins in experimental situations and unhesitatingly offered up as laws of classroom learning. Disregarding these latter misconstructions of the learning theory analysis (the price of popularity, which psychoanalysis has paid and which genetic epistemology is beginning to pay) one must accept the body of careful speculative extensions as an effort to display and justify the ultimate promise of the learning theories.

Keeping in mind these three levels of development of the Hull-Spence theory, one may suggest the linkages of that theory to

basic research on learning in child psychology. Since Hull's formal system, laid out on animal data and the data of human classical conditioning, was intended to portray universal processes of S-R bond formation in all species, it is at least conceivable that the system could have been superimposed on the results of suitable data-gathering efforts using children. This possibility has aroused little interest among child psychologists. In the formal sense, Hull's theory is a first approximation to what we today call mathematical models of learning (Spence, 1952, 1953). The later, tighter body of mathematical models has not drawn forth much research and development among child psychologists, only sporadic and casual occasional papers on children's probability learning (e.g., Messick and Solley, 1957, Ross and Levy, 1958, Stevenson and Zigler, 1958, Atkinson, Sommer, and Serman, 1960, McCullers and Stevenson, 1960, Kessen and Kessen, 1961, Siegel and Andrews, 1962, Brackbill, Kappy, and Stair, 1962, Craig and Meyers, 1963, Bogatz, 1965). If anything, the trend in child psychology is away from theorizing construed as mathematical modelling to predict behavioral probabilities.

The countervailing tendency among child psychologists has been to accept the exact analysis of the S-R bond as a given or as something to be worked out elsewhere and to concentrate efforts on the analysis of the more complex levels of behavior. At the second level of development of the Hull-Spence scheme, there is the discrimination analysis. Discrimination problems can be given to preschool children in formats quite analogous to those used with animals. Here, in the children's literature, one finds what little formal theorizing there is (Spiker, 1963, Zeaman and House, 1963) and here one finds a small reconsideration of the continuity-noncontinuity controversy resolved by the postulation of central stimulus-selection mechanisms. The newer analyses of the child in the discrimination situation run together with the newer analyses of the animal in that situation (Fellows, 1968, Ruly, 1968). But here, as everywhere, the child psychologist's adoptions of the instruments and the formal theoretical apparatus of the tradition are mostly not being used for the development of a formal theory, effort is concentrated

on those aspects of the discrimination situation which offer a jumping-off place for the exploration of factors of attention and symbolization. Examining the spectrum of S-R efforts in the time of the new American revolution, this seems predominantly to be the case. Most of the work in child psychology is at the third level of development of the Hull-Spence analysis, the attempt to "open up" the theoretical scheme to make it a vehicle for the understanding of significant issues in human behavior. There are a series of such programs, which can be seen as attempts to modify and enlarge the analysis to accommodate it to the human factors and the developmental factors with which the child psychologist must deal.

Analysis of the Stimulus

The problem of the exact definition of the stimulus arises before one attempts to bring the S-R analysis to human behavior, it is a fundamental issue for that analysis, never really resolved. In an early paper, Skinner recognized the problem.

In the description of behavior it is usually assumed that both behavior and environment may be broken into parts, which may be referred to by name, and that these parts will retain their identity from experiment to experiment. If this assumption were not in some sense justified, a science of behavior would be impossible. (Skinner, 1935, p. 40)

Despite the truce with the problem worked out by Skinner in that paper, the problem of the stimulus, the "environment broken into parts," has persisted for behavior theory. The problem is that one cannot seem to find a part of the environment which in and of itself, disregarding the subject, is always a stimulus for behavior. In recent years, S-R psychologists within and without child psychology have tried to grapple with the issue of the definition of the stimulus and, in so doing, have reintroduced the term "attention" to behavior analysis.

Stimulus Salience In all behavior analysis, it has been recognized that some parts of the environment are more likely to be stimuli than others because of intrinsic properties of intensity, change, size, etc. In a recent, influential book, Berlyne (1960) attempted an

examination of the issue of attention, orienting, and stimulus selection. With the publication of that book, an interest in what he has termed "collative variables" of novelty, change, complexity, conflict, surprisingness, and structure has developed in the subsequent experimental literature. Cantor (1963) has provided a review of research directed at substantiating the special saliency of complex and novel stimuli for children's behavior.

Berlyne's analysis is less concerned with the intrinsic properties of environmental events which cause them to draw attention, and more with attention as it is determined by a strategic interplay between what the environment offers and the central structures within the subject. Several researchers have been concerned to show that the efficacy of a stimulus may be altered by the subject's history with it. Cantor and his associates have explored what seems to be a stimulus satiation effect upon reaction time (Cantor and Cantor, 1964, 1965, 1966, Witte and Cantor, 1967, Bogartz and Witte, 1966, Witte, 1967). Another set of studies has shown that stimuli which are associated with rewards acquire salience for the subject (Nunnally, Stevens, and Hall, 1965, Nunnally, Duchnowski, and Parker, 1965, Parker and Nunnally, 1966, Nunnally, Duchnowski, and Knott, 1967, Nunnally and Faw, 1968). Such experiments begin to introduce conditionality into the effectiveness of a stimulus. Despite their obvious relevance, experiments which attempt to monitor at least the overt accompaniments of the stimulus selection process, scanning behavior, are still few (White and Plum, 1964, Wright and Smothergill, 1967). Such experiments would obviously be useful in providing a bridge between the kinds of stimulus-enhancing and stimulus-diminution factors suggested in the Cantor and Nunnally series and the dimension-selecting mechanisms which are proposed to exist in the Zeaman and House theory.

The S-R tradition has thus made an acknowledgment of attentional factors when they are determined by the intrinsic saliency of the stimulus, by the overt scanning of the subject, or by the relatively recent history of the subject with the stimulus. Berlyne's theoretical analysis goes further, of course, but it seems significant that subsequent experimental work has been so heavily directed

toward the novelty and complexity of stimuli, the most "out there" of his collative variables. Other collative variables depend upon the postulation of central mechanisms which effectively select those parts of the environment that will be stimuli, central structures which have as yet been given no detailed and incisive representation in the S-R schematization. We turn now to an examination of some of the recent attempts to approach such central terms.

Attempts to Model Conceptualization, Inference, and Planning

As has been suggested earlier, the original basis on which the learning theories were established in psychology was once to provide a step-by-step empirical route toward the analysis of complex human adaptive mechanisms. A good number of the early theoretical writings of Tolman and Hull were directed to offering behavioristic or S-R accounts of higher mental processes, and continuous with the history of the S-R tradition there have been numerous attempts to provide accounts of expectancies, sets, concepts, inferences, and strategies within the scope of the system. Within child psychology, one finds representations of some of these efforts. It seems significant that despite the long history of S-R attempts in these directions, so much of the present work seems at its beginning, tentative and prefatory. Where a large literature has developed, as is the case with the mediation hypothesis, it has eventuated in very little systematic development.

Discrimination Learning Set. Stemming from Harlow's work with animals, there has been some exploration of the phenomenon of learning set with children and the work with children has largely substantiated what has been concluded from the animal studies. Experiments have demonstrated cumulative nonspecific transfer—learning to learn—from one discrimination problem to the next, and they have suggested that such transfer is associated with the progressive suppression of position-guided strategies and, possibly, some change in the visual search patterns of the child as he moves from one problem to the next (Reese, 1963).

The present-day efforts, with animals and children, represent a more or less rigorous realization of the view of the discrimination

learning process suggested by Lashley and Kiechevsky some decades ago. Partly as a result of this realization, there are newer models of discrimination learning which blend together noncontinuous factors (stimulus analyzer selectors or dimension selectors) with continuous learning processes (Sutherland, 1959; Mackintosh, 1965; Zeaman and House, 1963). These provide that the organism can switch attention from one type of cue to another in the course of learning and provide a partial accommodation to the data at hand. The error factors appear to involve something more than inappropriate stimulus control over the subject's behavior, and this residual has not yet been incorporated into the theorizing. There are different strategies, or stereotypes, which can follow when subjects are position-guided and the systematic treatments do not offer a differentiation among the strategies. Furthermore, there are age changes in proneness to selection of a strategy (Wen, 1964; Levinson and Reese, 1967) which need explanation. The learning set analyses seem to have forced the establishment of enough central processing to account for central switching from one stimulus dimension to another and sudden learning; they have opened issues of strategy selection and age change, but no extensive analysis has been given to those issues in this line of work. There are other avenues which do lead to formulations concerning temporally organized response sequences and age change with respect to their use.

Mediation Theory By far, the most extensively explored issues in the S-R literature of child psychology have to do with a pair of age shifts in learning occurring in children between 5 and 7 years of age. There have been hundreds of investigations of a change in the child's reaction to the transposition experiment in this age range (Kuenne, 1946) and a parallel change in reversal-nonreversal shift problems (Kendler and Kendler, 1962). This literature has mostly been concerned with whether such phenomena can be accounted for by central mediational processes (Kendler and Kendler, 1962; Reese, 1962), by age changes in attentional processes (Zeaman and House, 1963), or the development of stimulus differentiation (Tighe, 1965; Youniss and Furth, 1965). However, as one examines the voluminous literature on these problems

one is more impressed by the number and complexity of the side issues they have engendered than by their tendency to converge on some decisive clarification of the source of the original experimental effects (White, 1963; Zeiler, 1967; Weiss, 1967). White (1965, 1966a, 1966b, 1968b) has suggested that these age-shifts in learning experiments are part of a large spectrum of change in the 5-7 age range, involving not only many other behavior changes but also changes in physical growth and in susceptibility to pathology. One implication of such an analysis might be that these experimental situations and their variants offer too narrow a window through which to explore the underlying developmental process. Certainly, however, some facets of development could and should be better revealed by an examination of the changes in learning.

It is quite common for experiments in the learning theory tradition to uncover phenomena reflecting developmental changes or cognitive phenomena, and it is always an intriguing issue to try to handle them in some sort of systematic way. The issue, always, is whether such special phenomena, now located and demonstrable within an experimental S-R format, can be shown to have some explanation which is intrinsic to the S-R scheme. In terminology with which we have all become familiar, the issue is whether the S-R schema can be adapted to an observed novelty through assimilation or accommodation. To assimilate is essentially to account for the phenomenon in the terms of the theory, thus a broad set of phenomena in classical conditioning and associative transfer has been linked to some quantitative assumptions about drive-habit interaction in Hullian theory (Spence and Taylor, 1951; Spence, 1956; Castaneda, 1965). To accommodate, on the other hand, is to make some alteration in the theory which remains within certain ground rules basic to the construction of the theory, the ground rules are essentially, the assumptions that form the "learning theory point of view," discussed earlier. Spiker's stimulus interaction hypothesis (1963) and Zeaman and House's attentional theory (1963) are examples of permissible alterations. Failure to adapt, to either assimilate or accommodate, would be represented by a concession to maturational or central causation not portrayable in S-R terms and

not moved by the dynamics envisaged by the system

Bearing in mind that the ultimate thrust into higher mental processes was the long-range goal of the Hullian system, the transposition and reversal-nonreversal shift phenomena have a special significance

First, given a system which is largely built upon animal problem-solving, it is significant that these age changes between 5 and 7 seem to represent shifts from the approaches to these problems characteristic of animals toward the approach characteristic of human adults. If one could identify what is new in the older child's approach, one would probably have located a significant human factor

Second, there is a relationship of these age shifts to language which strikes peculiarly closely to a long-suggested human factor. Children to show the older pattern of performance often give, or can be made to give, labels for stimuli that might lead them to the older behavior. These labels can be conceived of as the "pure stimulus acts," or response-produced cues, which behavior theorists have consistently postulated, in animal experiments as well as human, as a rigorous systematic basis for phenomena of anticipation, expectancy, or symbolization (Hull, 1930, Osgood, 1953)

Thus children in this age range make a move toward adultlike performance, and they do so in a way that suggests that response-produced cues might be fairly employed as a theoretical accommodation to the phenomena. The issues now reside in the fine grain of the data and, as well, in the fine grain of the hypothesis. There are ways in which verbalization might lead to the age shifts which would fit tightly neither into the theoretical framework nor, perhaps, within the ground rules (Vygotsky, 1962). One must elaborate the mediational hypothesis so that it describes not only the "before" and "after" learning processes, but also the mechanism of age change. Reese (1962), staying within the system of discourse, suggests overturning as an explanation, but Kendler and Kendler (1962) suggest that it must be due to development, maturation and experience, conceding to factors outside the system. If labeling does not always accompany the older pattern of performance, and if teaching of labeling does not always produce it, it is

possible to hold that verbalization is not a cause but a correlate of the age-shifts, and to suggest as an alternative that changes in the attention of the child might account for them. Complicating the problem of decision among the overlapping theoretical alternatives is the fact that the experiments in this area regularly turn up odd experimental effects, which now form a good-sized family of unsolved side issues

The voluminous and tortuous literature which all this has generated has not yet brought off the proof that the S-R scheme explains the older child's pattern. That explanation, even if successful, would really give the system little thinking power. What would be installed in the center would be a mediating word or act, cued as a response by the external stimulus, giving to the subject the ability to make a response not determined by his reinforcement history with the external stimulus

Part of this limitedness is unnecessary in learning theory terms. It arises from a deceptiveness in the diagrammatic form in the S-R scheme, recognized in other contexts but not often brought up in discussions of children's mediation. The prototypical episode in Hullian theory begins with an S, or groups of Ss, moves through the intervening variables, and ends with an R. However, behavior theorists have had to recognize that, even in the simplest learning situations, the sequence S-R is an abbreviation for a sequence of behavioral episodes which must properly be diagrammed in some form like $S - R_1 - S_1 - R_2 - \dots - R$ (Spence, 1956, p. 44). Diagrammed at full length, what behavior theorists have called an S-R connection becomes an organized assembly of adaptive behavior virtually identical to what Piaget has called a sensorimotor schema, and the mediational properties of a "response-produced cue" become—what? Perhaps something like the plan of Miller, Galanter, and Pribram (1960), perhaps something like the orienting-investigatory schemata of conceptualization of the Russians (Zapozhzhets, 1961), perhaps something like the operation of Piaget (1960)

There is no explicit theoretical treatment which develops the possibility of a mediational use of a nonabbreviated S-R connection, but one can imagine a number of interesting

possibilities. Any one of them would make the issue of mediation more complicated, richer, probably even less able to be settled by empirical test, than the question whether the child does or does not depend upon cue words like "larger" and "smaller" in his vocabulary. But it would instantly move behavior theory closer to comprehending findings like those of McKee and Riley (McKee and Riley, 1962, Riley and McKee, 1963, Riley, McKee, and Hadley, 1964), who have shown that transposition implies more general ordering ability than would be implied by the possession of locally appropriate ordering labels.

Inference and Reasoning There has been some effort to examine the ways in which S-R links might be strung together in sequences, to form a basis for what are usually called reasoning and planning.

One line of work has produced a sequence of studies directed at children's inference. The sequence of studies has been reviewed in Kendler and Kendler (1967) in a close-knit analysis which is, in itself, a model of the process of experimental inference; the paper offers a superb example of the programmatic development of an idea through a succession of procedures and experiments. The searching serial quality of the set of studies reported in this paper is worth some emphasis. A problem which plagues the learning theory tradition because of its closeness to procedures and emphasis on testable hypothesis is the very readiness with which any issue draws swarms of "one-shot" literature entries—studies which must be accommodated because they do, after all, present data but which are so raw and chancy in inception, execution, and interpretation that it is difficult to know what weight to place upon them. A collection of such studies addressed to an issue—e.g., transposition, the controversies about latent learning, place versus response learning, etc., can bring in so much noise that they hinder as much as help. Many one-shot studies are valuable, of course, and one could not draw a line which excluded the bad from the good. Nevertheless, one can safely argue that there has been, and is, too little of the thoughtful programmatic experimentalism manifest in the Kendlers' efforts, in Osler's analyses of concept attainment (Osler and Fivel, 1961, Osler and Triaufman, 1961, Osler and Weiss, 1962, Osler and Shapiro, 1964, Osler and Kofsky,

1965, 1966) and in Lipsitt's explorations of infant learning (Lipsitt, 1963, 1967).

The Kendlers' analysis of inference directs itself to Hull's analysis of reasoning, defined as "the joining of two-behavior chain segments previously learned on separate occasions so that together they solve a problem faced by the organism." In the course of their efforts, they come to the conclusion that Hull's formulation does not yield derivations valid for their data; they find that their test of reasoning shows a sharp increase in children between 8 and 12 years of age; they find interactions of inference with assigned verbal labels which lead them to conclude that verbal mediation has an important bridging function for the inference process. Again, their experimental analysis is quite precisely delimited, their theoretical analysis places in the center the simple labeling response or a response term like it.

we should again make explicit that representational responses are not synonymous with verbal labels. As far as we know, any response with adequate feedback could serve the purpose. We used linguistic labels for reasons already enumerated. It also seems likely that, among articulate humans, verbal labels are among the most common responses used for representation simply because they are so well suited to this function. They are so available, discriminable, easily fractionated, can occur without interference with any other ongoing activity, can so easily move forward in the behavior sequence (Kendler and Kendler, 1967, pp. 188-189).

The Kendlers, here as in their reversal-non-reversal analyses, stop short of the proliferative possibilities introduced by their vicarious cue-producing response. Presumably, a response-produced cue could produce another vicarious response-produced cue which in turn could lead to others and one could then conjecture branching sequences of invisible S-R links to serve as a basis for quite complex central mediating processes. The Kendlers and other behavior theorists have probably stopped short of this kind of expansion because it is obvious that one is instantly deploying the scheme into conjectural and untestable areas. But there is a neobehavioristic group spearheaded by Osgood and Berlyne

which has developed these kinds of constructions

Berlyne's recent volume *Structure and Direction in Thinking* must be considered a landmark in the S-R analyses of higher mental processes, with particular interest for child psychologists. Unlike other behavior theorists, who often set forth theoretical schemes on carefully delimited domains as though the only facts that needed adjusting to were the incontrovertibly proven facts and the only real issues were the precisely formulated issues, Berlyne is unusually catholic and wide-ranging in his acknowledgment of diverse facts, issues, and formulations. Although other behavior theorists have been timorous about venturing more than a pseudopod of S-Rism into the unobservable areas of human mentalism, Berlyne has been quite bold in doing so. The two big problems in the center are, probably, what we generally call attention and reasoning and in separate books Berlyne has made a significant effort to encompass each (Berlyne, 1960, 1965).

The directed thinking book hearkens back to the second most venturesome of the S-R systematists, Hull himself, and the ideas which Berlyne develops have their germs in early theoretical papers in which Hull was trying to foresee the ultimate possibilities of an S-R analysis (Hull, 1930, 1931, 1934, 1935, 1938). The theoretical structures which are used are familiar in the learning theory lexicon: habit, the fractional anticipatory goal response, stimulus generalization, the habit family hierarchy, and so forth. These are worked up to model sequential thought processes in a way which has been tried before, by Hull in the previously cited papers and by others (Maltzman, 1955; Staats, 1961). Berlyne, however, offers certain new interpretations of these speculative habit structures which enables them to be subject to operations, transformations, groupings, etc. At the heart of the effort is the union between the speculative scheme of reasoning of S-R and Piaget, but there is more to the synthesis than that. The system also gives a place to such factors as imagery, multiple sensory representation, and certain of the transformational devices of the psycholinguists.

The complete treatment needs to be read, if only because there is not much writing anywhere which is so broadly in tune with what

the issues are for an analyst of reasoning. There is, of course, something slightly outrageous about the casting of all this in the S-R terminology. One has obviously moved things a good distance away from the "learning theory point of view," empiricism, behaviorism, and the traditional view of parsimony. That the treatment is possible at all is due to a quality in the treatment of the terms "stimulus" and "response," which should really be more explicitly acknowledged in the learning theorists' use of them. On the one hand the terms have been used to denote empirical units, the "behavior and environment broken into parts," which Skinner (1935) was at pains to justify, and on the other hand they have had a logical status. The terms "stimulus" and "response" have come to stand for "if" and "then" in a calculus of sequential psychological contingency. On many occasions, the empirical and logical uses of the S-R terminology can be confused and confusing, but Berlyne's use of it makes a fairly clean break with the empirical side. Essentially, the innards of Berlyne's reasoning organism are wired with if-then statements, or systems of them.

Berlyne (1954) has freely admitted the difficulties with this speculative S-Rism, but he has argued that the rigor of the S-R terminology makes the effort worth a try. One cannot speak of empirical rigor in this kind of effort, but one can speak of a rigor of delineation of antecedent and consequence in hypothesized processing sequences. This is not the "right" rigor in the classical S-R sense, but there are plenty of cases in the history of psychology where right things have been done in the wrong way and wrong things have been done in the right way. This kind of effort is almost *sui generis*. It floats free of its origin and it needs to be judged on its own terms. Right now, it has some intrinsic interest for child psychologists because it has accomplished some important junctures among what might have seemed to have been incommensurable sets of independent analyses. It will not be testable and provable or disprovable in the usual sense in which we understand those terms. But it rests on facts and on reasonable interpretations of those facts; its linkages are quite reasonable; it has a form of truth value because of that. In time, we may know enough to rewrite it, make it closer to a larger

network of facts, locate it better in neural processes, perhaps give it more exact predictive and explanatory power. We have no alternative to a treatment like this, really, because we have not yet found any better way to build a behavior theory.

Attempts to Examine Social and Personality Processes

We turn, now, to a set of theoretical efforts in which the S-R scheme is brought away from its originating thrust toward human problem-solving, and we consider a set of efforts in which the S-R terminology has been brought toward the other great concern of psychologists in the first half of this century: a personality theory, an interwoven consideration of individual differences, social influences, and psychopathology. The originating development of the S-R scheme toward a theoretical account of personality issues was, again, out of Yale. Miller and Dollard's (1941) analysis of imitation, Dollard and Miller's (1950) account of personality and psychopathology, and Mowrer's (1950) treatment of personality. These larger efforts were accompanied by a large number of research efforts, using animals and humans, in which experimental techniques were developed to attempt to bring fear, anxiety, conflict, regression, displacement, fixation, etc., into the laboratory. There are obvious difficulties in establishing an experimental tradition around such topics with human subjects, but certain kinds of studies—of imitation, of social interaction effects—can be conducted in an experimental manner using children. Other topics are approachable through observations of co-occurrence, correlational methods. In recent years, still another empirical approach is at hand, in which a theoretical analysis is interwoven with an applied effort at behavioral or social engineering. Now we cannot speak of a laboratory tradition, we begin with speculative analyses which by their nature must touch empirical ground when and as they can.

The S-R analysis of learning and cognitive processes worked its way into child psychology through a number of spin-offs in which procedures and issues elaborated in the general experimental literature migrated into use with children. The learning theory approach to personality processes came in less adventi-

tously and it came in earlier. Robert Sears, concerned at first with the experimental testing of psychoanalytic hypotheses (Sears, 1943), became the first to organize a learning-theory-based analysis into child psychology and one can trace most of the efforts to provide an S-R analysis of personality development to his influence. His move into child psychology was a logical one. The conditions for learning are at hand to be studied wherever one can produce some learning, but the conditions for the development of personality would seem to be either in childhood or in genetics. Thus personality theories of the S-R stripe or any other variety must inherently be concerned about developmental issues.

Antecedent-Consequent Analysis of Child-Rearing Consequences. The development of an antecedent-consequent analysis of the growth of the child's personality would seem to have been built around three consecutive programs of research organized by Sears and his associates and described in three major reports (Sears et al., 1953; Sears, Maccoby, and Levin, 1957; Sears, Rau, and Alpert, 1965) and numerous collateral papers. Though these programs originated in an attempt to apply something much like the Hull scheme to socialization, a number of important modifications of the scheme had to be made to confront the problem, and it is questionable whether the final form of the efforts was in any vital way formally dependent upon, or a serious test of, the originating learning theory.

That Sears was initially concerned to develop a Hull-like theory seems clear in his presidential address to the American Psychological Association in 1951:

the data of social psychology have been meager and those of personality limited mainly to clinical observations.

Yet it is clear that further development in these fields will require an adequate theory. By a theory I mean a set of variables and the propositions that relate them to one another as antecedents and consequents. This involves such logical impedimenta as definitions, postulates, and theorems. And it requires the following of certain rules, such as that the definitions of variables must be mutually exclusive, that intervening variables must ulti-

mately be reducible to operations, that the reference events specified as the consequents in theorems must be measured independently of the antecedents from which they are derived and so on. The general procedure of theory construction is sufficiently standard that it needs no explication here (Sears, 1951, p. 476).

Sears' efforts have been most consistently concerned with the analysis of dependency and aggressiveness in children, dependency construed in the S-R scheme as a secondary reinforcement process arising because the parent is instrumental for and contiguous to the reduction of primary drives in the child, aggression analyzed in the terms of the frustration-aggression hypothesis, of which Sears was a co-developer (Dollard et al., 1939). In the analyses of child-rearing practices which were undertaken, characteristics of parents and homes were treated as independent variables and dispositions of the child, often far removed in time, were treated as dependent variables. In those analyses, consequently, Hull's analysis of the force field surrounding a single S-R episode would not be applicable and, instead, we deal with the causal connections between antecedents and consequents. The antecedents and consequents are not one event, but rather a string of events having a similar force as, for example, when a mother consistently punishes overt aggression and the child is regularly quite aggressive in doll play. In several significant ways, the approach of Sears and his group vacated the observational base of the learning theorists, slicing the stream of behavior quite differently, while retaining their concern for the dynamics and terminology of S-R analysis.

Sears (1951) has projected an even more radical departure of antecedent-consequent analysis from conventional behavior theory. He points out that personality and social psychology, concerned with interpersonal transactions, have need of *dyadic* theorizing which acknowledges the two-person interaction. This seems to be an argument that antecedent behaviors on the part of one person and consequent behaviors on the part of another cannot be fully comprehended without taking into account the fact that the individuals are in an established interdependency upon one an-

other and, consequently, react to one another's behaviors in terms of expectancies. The expectancies of the actors participate in the defining of what is to be an antecedent or a consequent.

The various translations of the Sears group, done or projected, move the grounds for discussion of their organizing framework a distance away from the originating learning theory tradition. In fact, the theory once hoped for by Sears has not yet come into being. His originating efforts had success in one sense, they did create a good-sized body of research on children's socialization. Probably, the development of theory has not taken place because deductive psychological theories do not seem as accessible a goal as they once did, and because studies of the effects of child-rearing practices and interrelationships of personality variables have not yet made it easy to see regularities across studies (Kohlberg, 1963, Caldwell, 1964). There are still-unsolved technical problems in observing such regularities.

Imitation and Social Reinforcement
Through the work of some of Sears' students, there have developed some other veins of research into social processes in childhood. These efforts are not directly derivative from Sears' antecedent-consequent approach. They are often characterized as social learning theory. They involve small-scale laboratory studies using children and in the ideas which guide them they make a fresh connection with the learning theory tradition.

Bandura and Walters (1963) have set forth an important new treatment of the imitative process in children. They, like Sears, emphasize consideration of the dyadic nature of human transactions and they point out convincing experimental evidence of the significance of imitation as a basic mechanism of learning. They suggest that some modification of the learning theories is necessary to account for this. Accommodation of the learning theory to imitation has existed for some time in treatments by Miller and Dollard (1941) and Mowrer (1950), but those treatments are essentially accounts of the establishment of the eliciting powers of the model through reinforcement. Experiments exist which support them. One can increase imitation by increasing the rewarding powers of the model (Bandura and Huston, 1961, Bandura, Ross, and

Ross, 1963) and one can, through reinforcement, increase the child's generalized tendency to imitate (Baer and Sherman, 1964). However, Bandura and Walters point out that individuals without any status in the reinforcement history of the child—strangers—can serve as models for imitation and that therefore imitation can serve as a generalized basis for the transmission of behavior patterns outside a context of reinforcement and nonreinforcement.

In the history of the development of learning theories, there somehow developed a consensus that there are two fundamental types of learning, in the Hull-Spence terminology called *classical* and *instrumental* conditioning and in Skinner's terminology *respondent* and *operant* conditioning. The assumption that there are only these two types has not been probed very extensively, probably because it is difficult to conceive of a direct test of the far-reaching assumption that one or two learning processes are the prototypes of all adaptation. One can ask if at least one of the two types is detectable in all species which give some evidence of learning, one can ask if at least one of the two mechanisms is detectable in infancy coexisting with the first clear signs of environmental adaptation, one can ask if all forms of adaptation which do not look like these two types are somehow reducible as special cases of them. The first two kinds of tests have been sporadically attempted (e.g., Hilgard and Marquis, 1940, p. 30–32, Lipsitt, 1963) without any strong contradiction of the existence of the basic dichotomy. With respect to the third test, things are more ambiguous, because it is always debatable whether or not an analysis of an observed adaptation does or does not successfully reduce it to the proposed basis. Thus, there now exist a set of observed forms of adaptation whose relationship to classical and instrumental conditioning has at best been conjectural: sensory preconditioning, habituation, stimulus predifferentiation, learning sets, sensitization, imprinting, and imitation. Several of these are of considerable interest to the child psychologist, because they imply accounts of the development of the child through experience not conceived as reinforcement history. Imitation, in one sense firmly linked to behavior theory, is a good case in point.

Bandura (1965b) has offered an incisive

and scholarly analysis of the mechanism of imitation and its influence, and his review sets the imitative tendency within the learning theory framework, with one or two amendments. Observational learning does require the assumption that imaginal and verbal representation of a model's behavior can be developed in the observer through contiguity, and that such representations can then serve as directions ("discriminative stimuli," "templates") for the organization of the observer's subsequent behavior. The tendency to imitate gives to the child a mechanism of "no-trial learning," Bandura's phrase, which would enable him through observation of others' behavior to develop new response patterns (Bandura, Ross, and Ross, 1961, Bandura, Gusec, and Menlove, 1966), modify his behavior according to the permissions and prohibitions in his environment, (Walters and Parke, 1964), and interpret his own emotional reaction to it (Schachter and Singer, 1962). Evidence that observation will accomplish these things has been provided in a great number of experiments (Bandura, 1965b). Imitation thus provides a basis for a broad spectrum of adaptation, and it could account for an enormous amount of the child's learning in life. Bandura argues that, in fact, it must be quite pervasive in its influence because of its efficiency, because there are so many kinds of adaptation to physical and social risks where trial-and-error learning would be inconceivable, and because the child learns so much for which it is difficult to imagine a reinforcement shaping history.

Whether or not the imitative tendency derives from the mechanisms of learning theory, the wide practical importance of imitation envisaged by Bandura would seem to necessitate a radical reorientation of experiment and theory having to do with children's learning. Most of our studies of children's learning are not intentionally conceived as dyadic. If imitative learning is a central factor, this experimental emphasis needs to change.

Most of the experimentation on imitation to date has attempted to demonstrate the range of effects it can have and it has been incidentally directed at establishing its precise linkages to processes of classical and instrumental conditioning. The delayed reproduction of the model's behavior requires that there exist within the subject imaginal and

verbal representations of the model's series of stimuli, which, in turn, serve as discriminative stimuli guiding the observer's reproduction. These, it is argued, are cue-producing symbolic responses developed according to the usual associative learning principles. Again, here, there is an appeal to central representational elements which, by the very nature of the imitative phenomenon, must be something more than the single cue-producing response conditioned to the single stimulus. This is a substantial admission of a central operator, though not all concede its necessity (Gewirtz and Stingle, 1968).

The radical theoretical reorientation provided by imitation comes where one tries to project outward from mechanisms and functions toward some kind of account of the child's development through experience. One does not have to search the child's history for hypothetical reinforcement sequences which could shape him toward adulthood, one imagines, in addition to this, an extensive influence of unreinforced observation of others. In so doing, the learning theory view veers abruptly toward the reconstructions of the cognitive development of the child offered by Piaget (1962) and of his psychosocial development by Kohlberg (Kohlberg, 1966), ostensibly treatments offered from a point of view quite different from the learning theory tradition. These offer free play to central operations, whereas the representational scheme offered by Bandura is used judiciously simply as a carrier of the model's earlier performance to the observer's later copy. If one assumes the possibility of central operations upon such a carrier, and it seems more likely than not that evidence for this could be developed, one forms an alliance with the constructions of Berlyne's neobehaviorism. All in all, the introduction of a mechanism of imitation would require a rather drastic revision of all previous projections from the learning theory framework.

Another large vein of research activity has been developed from studies of a special dyadic situation, conceived as a paradigm for the study of social reinforcement. In this situation, the rate at which a child performs a simple repetitive response, his baseline, may be increased or decreased by supportive comments delivered by others. This measurement of the effectiveness of a social stimulus

through its ability to deflect ongoing steady behavior is analogous to a technique widely used for the study of fear in animals, where the effects of a fear-evoking stimulus are measured by its ability to elicit cessations in a stream of positively rewarded responses (Estes and Skinner, 1941). Here, the development of a considerable body of data reflecting manifold and complex social influences upon the child's behavior has been, so far, an inductive process without much accompanying theoretical development (Stevenson, 1965). The experimental paradigm is treated curiously like a behavioristic projective test for uncovering the effects of social motivation. Not all are agreed that a social motive, per se, is involved. One issue, an effect of isolation on social reinforcement first described by Gewirtz and Baer (Gewirtz and Baer, 1958a, 1958b, Gewirtz, Baer, and Roth, 1958) has led to extended replication and the development of several possible lines of explanation of social influences in this situation (Walters and Ray, 1950, Erickson, 1962, Stevenson and Odom, 1962, Hill and Stevenson, 1964, Lewis, 1965, Rosenhan, 1967, Landau and Gewirtz, 1967, Gewirtz, 1967). These offer, in microcosm, a spectrum of S-R treatments of social influence in the contemporary literature.

THE EXPERIMENTAL ANALYSIS OF BEHAVIOR

In our discussion of the learning theory tradition in child psychology, we have been using an organization which simplifies discussion but is slightly inaccurate. We have discussed basic research and theory building largely as derivative from the Hull-Spence tradition, and we will now proceed to discuss the experimental analysis of behavior ("descriptive behaviorism," "functional analysis," "operant analysis") largely as a platform for applied efforts. Within child psychology, the pattern of contemporary work is mostly arranged this way—though one must note the existence of behavior therapies built from the Hull-Spence analysis or extensions of it (e.g., Wolpe, 1958, Bandura, 1961, 1965a), and theoretical arguments using the viewpoint of functional analysis (e.g., Gewirtz, 1961, Gewirtz and Stingle, 1968). The divergence between the two treatments of stimulus-response

analysis is substantial and there is a sense in which it almost subsumes the applied-basic distinction. Functional analysis searches for those environmental conditions which control the animal's behavior; the behavior theorists are always concerned with the adequacy of a network of postulated relationships among variables. One tries to manage the subject and the other tries to explain him; these differences in approach are there whether the view is toward basic or applied problems, and whether the topic is learning or social behavior.

Again, here, we deal with an S-R program that was first well developed outside child psychology and which then exported component efforts into it. The general systematic stance of the program is familiar to most psychologists (Skinner, 1938, 1953, 1959b, Keller and Schoenfeld, 1950, Holland and Skinner, 1961, Hilgard and Bower, 1966, Reynolds, 1968). Despite the popularity of the approach of experimental analysis, there are not many ideological fissures within the group subscribing to the program. On the surface, at least, this is a movement which deliberately travels light theoretically and perhaps because of this it has not generated the proliferation of idiosyncratic analyses and speculative theorizing which now has acted to partition off subgroups of individuals who have become specialized in their commitment to behavior theory. To a rather remarkable extent, the individuals committed to functional analysis have held to those thrusts set up by Skinner.

A good deal of the uniqueness of functional analysis seems to have been laid down in a special treatment of animal research, first fully described in 1938 in Skinner's *The Behavior of Organisms*. An animal is brought to repeated delivery of an index response by a shaping procedure in which successive approximations to the response are rewarded. When the animal regularly delivers the response, his rate of delivery—the basic datum of this method—is subject to manipulation by various schedules of reinforcement, fixed programs of reward contingency and time interval which govern whether and when the running responses of the animal will bring a reinforcement. When an animal adopts a stable and characteristic pattern of response to the schedule, the schedule is said to con-

trol his behavior. Similarly, when a stimulus, signalling the enforcement of a particular schedule, influences the animal's behavior, there is said to be stimulus control. There may, also, be compoundings of stimuli and schedules offering too much intricacy for straightforward adaptation by the animal, then a second-order shaping process is devised in which one begins with a simple schedule and moves to successive approximations until the animal is adapted to the multiple schedule. This constant emphasis on control "sets" the system in the direction of the behavior engineering efforts toward which it has tended. Where the traditional motto of hard-nosed psychology has been "Predict and Control," a different kind of scientific determinism is called into play here, a determinism in which one controls and therefore predicts.

Method, this method of working with subjects, is one important unifier of those interested in the experimental analysis of behavior. There has been sustained laboratory exploration of schedule effects accompanied by the innovation of new schedules. Some of the schedule information has been codified in a large handbook (Ferster and Skinner, 1957) and, since 1958, more has appeared regularly in the *Journal of the Experimental Analysis of Behavior* devoted almost exclusively to the development of the method. Some have argued that the widespread influence of Skinner's systematic writings has been brought about by the utility and versatility of his experimental procedures. Such an argument has a little evidence going for it. Skinner's experimental chamber is an unusually convenient way of gathering behavioral data from animals: simple, automatable, sensitive, and flexible, it has been given extensive technical development, and it is now one of the bread and butter items of the psychological equipment industry.

Despite all the obvious usefulness of the operant paradigm, it would be a serious underestimation of the intellectual force of the program built around it to see that program only as sophisticated gadgetry with an ideological penumbra. The program, by choice, does not espouse a theory of behavior (Skinner, 1950). However, a unique approach to the study of behavior has been gradually developed in association with the

instrumentation which, if it is not a theory, at least stands in serious competition to other approaches which include theoretical proposals

Operant Conditioning Paradigm and Approach

Skinner (1959), in a classic piece of scientific autobiography, has been kind enough to the future psychologist to give a straightforward chronological account of the development of his paradigm. The paper has a wry quality characteristic of much of Skinner's writings, it tells a candid story of the bumbling, chancy process of scientific discovery in the laboratory, and that story takes on satiric overtones because it is given in response to a rather solemn and formalized survey of the methodological status of psychology. This mixture of seriousness and satiric irreverence extends beyond Skinner, it is a part of the style of the experimental analysis movement, which we will have occasion to refer to again. We know from the paper, at any rate, that the development of the paradigm was not a calculated innovation in psychological outlook. That innovations flowed from the method would confirm a point which Skinner might like: new behavior by the experimenter is tantamount to new thinking by the experimenter.

Used as a basic research instrument, the operant conditioning paradigm has some unique features which may set the stage for some of the uniquenesses in the generalized approach of the experimental analysis group.

Subject-Experimenter Relation. The operant conditioning technique has a peculiar immediacy which is a little difficult to describe, one must see the technique in operation for a while in order to appreciate it. A frequent objection to the paradigm is that, figuratively and often literally, it obscures the animal. The animal, shut inside an experimental chamber, becomes a featureless thing to which one pumps in cues and pellets and from which one gets the movements of counters and pens. The charge is that the experimenter has avoided the opportunity to be enlightened by naturalistic observation of the animal, as to a certain extent he has, but a peculiar reverse compensation emerges. In no other experimental format are the hard data so much on line with the experimenter's ac-

tivity. In most experimental formats, the experimenter will not fully see the force of his data until some time after he has seen his subjects, he must group, average, compute, plot, to know exactly what the subjects did. In the operant conditioning paradigm, the experimenter facing his buttons and switches and cumulative recorders is virtually in dyadic relationship with his subject. The subject's behavior shows a certain rate of response, the experimenter changes something, the animal very soon begins to visibly change his behavior pattern. One suspects that in the experience of this immediacy may be the origin of the word "control" so widely used in experimental analysis.

Procedural Flexibility. Most psychological research formats are what one might call testing formats, in that a fixed procedure is applied to a group of subjects who do more or less adequately in response to its demands. In the operant conditioning procedure, perhaps because of the immediacy which we have just discussed, procedure is often not fixed but rather there is an informal feedback from the subject's behavior to the procedure. The experimenter is flexible and opportunistic in his initial shaping of the animal's index response and, similarly, he proceeds by reasonable-seeming steps in his attempts to make various schedules assume control over the subject's behavior. Here, too, we arrive at an estimate of the subject's capacity but we make that estimate in a training format and the estimate has somewhat different implications. On the negative side, one must accept the fact that the training format is not only an estimate of the capacity of the subject as adapter but also, to some extent, of the capacity of the experimenter as trainer. On the positive side, the experimenter is given the flexibility to probe freely, to find out just what environment it takes to get the adaptation, and to get a more rounded picture of the exact circumstances upon which the adaptation depends. In principle, the sequential probing necessary for this could be done using judicious sequences of fixed-procedure experiments but this is time consuming and, in practice, such follow-through experiments are rarely executed.

Single Case Work. Operant conditioning typically generates relatively great quantities of recorded responses from a single subject,

and this stream of responses graphed on a cumulative recorder is, in effect, "smoothed" so that stable patterns of responding are seen in the single case record. In the more usual experimental formats, one cannot have objective, visible pictures of trend unless the records of a number of individual cases are averaged together. Moment-to-moment aberrations of the individual's response are in either case washed out—in the case of operant conditioning washed together with the individual's later responses, in the more usual formats averaged with the responses of other individuals. The latter device, grouping across individual differences, presents some known problems because group trends may be mischievously fictitious representations of behavioral regularities (Sidman, 1952). The classic case in psychology is where one way of grouping data leads one to talk about a gradual learning process, and another way to consider sudden learning (House and Zeaman, 1960, White and Plum, 1964). It is true that experimental analysts have been prone in the past to accept the results of one or two well-worked case studies to be generalizable to all individuals (or, occasionally, to all species), but this is not an intrinsic flaw of the method.

Behavior, Dispositions, and Time The ability of the operant conditioning format to picture stable trends in the individual subject is of some importance because this, in turn, brings about a subtle but important reorientation to psychological terminology. Much more than any other psychological paradigm, the operant conditioning paradigm develops information about the subject in real time. It deals with rate of reaction, behavior-and-time, rather than behavior frozen, sectioned, and stained. Temporal and frequency characteristics are "in" the descriptive terminology. Most other psychological work envisages a typical situation, a test or a trial, conceived as something administered to the subject to probe his dispositions to behave. One has repetition of the "same thing" over time. The Hullian theory, as we have seen, poses its entire theoretical analysis as an analysis of the vectors that impinge on the subject's behavior in a prototypical trial. To abstract behavior from the flow of time in this way leads one, seemingly inevitably, to reified nominalizations. Some characteristic of the subject leads one to conclude that the subject is some-

thing—intelligent, anxious, creative, fearful, rigid, retarded, mature, immoral, etc., etc. It then takes repeated sophisticated dialectic to keep the term in proper bounds, to keep reiterating that most statements of psychological disposition in the subject are not measurements of some part of him or truth about him, that a dispositional statement in psychology usually states some probabilistic consistency in a subject that depends upon a situation for its manifestation and that it usually alludes to some characteristic which he shows relatively more frequently than others. Operant analysis, which looks at adaptation as an increase or decrease of rate from baseline, which does not deal with the typical but the recurrent, somehow has a natural way of keeping psychological nominalizations on what would seem to be a more realistic plane of discourse.

Descriptive Behaviorism We turn finally, to the last special characteristic of experimental analysis, one that seems linked to the special set toward terminology given in this approach. All stimulus-response psychology emphasizes parsimony and edges toward nothing-butism, but the experimental analysis tradition is easily the most radical in its insistence on purely behavioral terminology. Not only the soft words which give all psychologists trouble, but also the ordinary little English words ("need," "try," "see," "want"), or the terminology of behavior theory ("habit," "drive," "motive," "fear") are frequently given semantic quotes in the writings of the experimental analysts. Terminology which asserts or implies central states of the subject is thus consistently handed to the reader between thumb and forefinger, as something which it is necessary to use but which one really cannot fully accept. At the same time one is given redefinitions in those writings, again and again and again, like a litany.

When a man controls himself, chooses a course of action, thinks out the solution to a problem, or strives toward an increase in self-knowledge, he is *behaving* (Skinner, 1953, p. 228).

To the question *What is drive?*, we must now answer that drive as the *name* for a fact—the fact that certain operations can be

performed on an organism (for example, depriving it of food) that have an effect upon behavior which is different from that of other operations. Drive is not a *thing* (Keller and Schoenfeld, 1950, p. 265)

The debunking quality of these repeated disclaimers from time to time joins with the wry style of the group to produce what seem to be calculatedly barbaric allusions.

Most operants occur with a high frequency only under certain conditions. One rarely, if ever, recites the Gettysburg address unless faced with an audience of listeners (Reynolds, 1968, p. 9)

The reinforcers portrayed in Heaven and Hell are far more powerful than those which support the "good" and "bad" of the ethical group or the "legal" and "illegal" of government control, but this advantage is offset to some extent by the fact that they do not actually operate in the lifetime of the individual.

In actual practice a threat to bar from Heaven or to consign to Hell is made contingent upon sinful behavior, while virtuous behavior brings a promise of Heaven or a release from the threat of Hell (Skinner, 1953, p. 353)

To most psychologists not soaked in this style of discourse such statements have a startling quality. The classification of the Gettysburg Address as an "operant" instantly brings to mind all of the qualities of the Gettysburg Address which the author of this quotation is not taken into account. The portrayal of Heaven and Hell as cosmic techniques for religious control seems like jargonistic imperialism carried off into infinity. But, by and large, this is a group which when writing outside its own technical journals is rather sensitive to words and jargon. One concludes, eventually, that there is a certain base rate of leg-pulling, a certain generalized willingness to put grandiosity and pomposity in its place wherever the occasion occurs, in such writings. But it all has a serious edge. Directly and indirectly, seriously or half-humorously, the experimental analysis group maintains a steady attack on the psychological discourse of everyday language and of everyday psychology, which it conceives of as a flawed lexicon

where descriptions of behavioral events are mixed with gratuitous and often unrecognized assumptions.

In the preceding discussion, we have tried to deal with certain specializations of outlook which have become associated with the experimental analysis of behavior. These are seen as capitalizations upon the new outlook offered by the method of operant analysis which, in the aggregate, amount to a new way of doing business with psychological data (Sidman, 1960). As experimental analysis has moved into child psychology, its proponents have developed a pattern of effort quite different from the work built out of behavior theory.

Functional Analysis of the Child's Behavior

In the dozen years or so since the experimental analysis of behavior has been brought in volume to the study of children's behavior, it has undergone a rather rapid evolution. Beginning in the middle 1950s, Bijou (1955, 1957, 1958a, 1958b, 1961, Bijou and Sturges, 1959, Bijou and Baer, 1960, Bijou and Orlando, 1961) published a series of laboratory reports which described the beginnings of a laboratory exploration of schedule effects with children, but the development of such a laboratory effort quickly abated in the child psychology literature and laboratory work is not, at this writing, prominent in the emerging literature. In its place, there has come a second wave of development of applied efforts toward behavior modification.

The deployment of techniques of behavior modification is at this moment proceeding with great rapidity. An increasing body of reports now exist which demonstrate some effectiveness of behavior modification across a good sample of problems and subject characteristics. In work with diagnostically normal children, there have been reports of obtained improvement in cases of regressed crawling (Harris et al., 1964), vomiting (Wolf et al., 1965), mutism (Kerr, Meyerson, and Michael, 1965), prolonged crying (Hart et al., 1964), isolation or timidity in play (Allen et al., 1964, Johnston et al., 1966), tantrums (Williams, 1959, Wolf, Risley, and Mees, 1964), and stuttering (Goldiamond, 1965). At the same time, behavior modification techniques have been brought into use with various diagnostic groups and there has been some

demonstrated improvement of behavior problems of handicapped children (Meyerson, Keil, and Michael, 1967), brain-injured (Hall and Broden, 1967), retarded (Burnbauer et al, 1965, Wiesen et al, 1967), autistic (Wolf, Risley, and Mees, 1964, Metz, 1965), and schizophrenic patients (Lovaas et al, 1965, Hingtgen, Sanders, and DeMyer, 1965). Behavior modification techniques have been brought to educational issues and used for remediation of reading problems (Staats et al, 1964, Staats, 1965) and for the betterment of the classroom group's functioning (Zimmerman and Zimmerman, 1962, Brown and Elliott, 1965, Mithaug and Burgess, 1967, Quay et al, 1967). Here the movement toward behavior modification joins another great applied offshoot of experimental analysis, the movement toward programmed instruction. We come almost full circle when we find fine-tooled programming efforts which have a searching quality and an analytic edge usually thought to be characteristic of the best "basic" research (e.g., Sidman and Stoddard, 1966, 1967, Stoddard and Sidman, 1967, Stoddard, 1968, Touchette, 1968).

The conveying of experimental analysis out of the laboratory and into a series of applied efforts raises several interesting questions. There is nothing unique to child psychology about this trend to practical intervention. The applied efforts in child psychology are part and parcel of a movement toward interventive efforts led by Skinner and characteristic of the group interested in experimental analysis. For most psychologists, this leap from the laboratory into application violates the expected. The traditional wisdom says that scientific development proceeds by a crystallization of basic research information into systematic theory and then by an extension of theory to the design of solutions for practical problems. There is a rhetoric in the behavior modification and programmed learning which goes toward this model. The applied efforts are sometimes said to be applications of "laboratory principles of learning." Such claims are usually dropped into discussion without elaboration and, in truth, one familiar with the psychological learning literature has a hard time finding backing for it. The centerpiece of psychology's conception of learning, the law of effect, is hardly a discovery of the twentieth century or a novelty in human en-

gineering. The lore of the research literature—the regularities and laws and curves—does not seem to have manifest value for application nor is its presence easily detected as an influence on behavior modification efforts. Without the backing of laboratory proofs, the traditional wisdom would tend to question the legitimacy of the scientific validity of such work.

However, one feels distinctly uneasy about the dismissal of such efforts as scientific adventurism. The traditional wisdom presupposes basic research as an enterprise cumulating hard, systematic data, which gradually give an explanation or an understanding of the critical issues of a discipline, the point of the learning theory movement seems to have been to set up exactly that kind of cumulative enterprise, and one point of the second American revolution seems to be that learning theory failed to be convincing in its efforts. One can, more generally, ask whether the basic research of psychology has yet shown the trend towards utility. One can ask whether the applied versus basic distinction in psychology can be given full credence. Do we really get more incisive information about human behavior from within than from outside the laboratory? Have psychoanalysis and psychometrics taken more from the laboratory than they have given to it? In view of such reservations, it is conceivable that here, as elsewhere, one finds Skinner finessing the traditional conceptions of scientific development of the discipline to work from an intuitive, and perhaps truer, conception of what moves it is possible for psychologists to make.

What has come from the laboratory into behavior modification? Not a theory. Not laws of learning, as they are usually conceived. What has come from the laboratory is an analytic posture, the tendency to construe behavioral affairs as a history of recurrent responses moderated by contingent reinforcement influences, and some methods of manipulating such responses. In two small books, Bijou and Baer (1961, 1965) have given a rough sketch of the child in his environment, giving full allowance to biological and maturational factors, but essentially arguing that the impingement of the environment upon the child's behavior and his adaptation to it can be envisaged in terms of his reinforcement history—that is, in terms of respondent and operant conditioning.

and certain elaborations of those mechanisms which lead to discrimination, differentiation, and chaining. A sweeping regularization of the child as a behaving system is involved. "The developing child may be adequately regarded, in conceptual terms, as a cluster of interrelated responses interacting with stimuli" (Bijou and Baer, 1961, p. 14).

This is the analytic posture of experimental analysis toward the child. It is a less simple posture than it would appear to be on the surface. The stimulus and response are observable events, parts of behavior and environment, but which parts are germane to the psychologist are selected empirically in terms of observed functional relationships. A stimulus or a response enters into the psychological analysis only when it has been shown to enter a functional equation. In a peculiar way, without relinquishing a positivistic stance, the analysis embraces a phenomenological point. The subject participates in the definition of what is a stimulus for him. Stimuli and responses are grouped into equivalence classes in a similar way, by empirically observed functional equivalence. This device, in turn, allows the system to collect disparate observables into types or syndromes without tying them together through a central mechanism or state. Some would argue that these definitional devices go a long way around to avoid what seems obvious: that there is a center, which accomplishes these special selections of stimulus and response. It may be said, however, that the analysis simply asserts in a principled way what most psychologists actually do in their development of nomenclature for environment and behavior.

With the developing child so pictured, his response patterns, seen as a set of operants, become manipulable in much the same way as the index response of the laboratory. Hypothetically, at least, they should be subject to shaping, extinction, and the effects of various schedules, just as the pigeon's window pecking or the rat's bar pressing operants. Unlike the laboratory case, of course, one does not have one's subject on a deprivation schedule; the child subject is not working for food or water or shock avoidance. The experimental analysts working with children have therefore had to be concerned with the critical question of reinforcement controlled by the

experimenter. Money, food, and tokens have been used in some cases. In most, the behavior modification efforts have relied upon the most natural and ubiquitous source of contingent reinforcement in the human environment, the approvals and disapprovals registered by teachers, parents, peers, or experimenter. The approach that weaves all this together into an applied program builds from the unique emphases of the laboratory approach, the set toward control, the procedural flexibility, the willingness to work with single cases, and the stress on behavioristic exemplification of nominalisms.

The positivism in which this work is conceived makes it difficult, at this stage, to discern how the behavior modification efforts can or will contribute to some betterment of our understanding of the child. The understanding of learning, or of the development of the child, upon which the movement now proceeds is, from the perspective of most psychologists, relatively rudimentary; the movement sets aside most of the enormous mass of information and speculation about learning and development whose significance now bedevils the understanding of the mass of psychologists. It seems to get along without it. In some writings, there is an edge of hostility toward traditional psychological terminology, which is seen as mystifying or obscuring matters that are straightforward when they are examined in behavioral terms. Meyerson, Kerr, and Michael (1967) quote an imaginary dialogue about mental retardation in this spirit:

"Why doesn't Mary walk?"

"Well, she's severely mentally retarded, and it is not uncommon among the severely mentally retarded that they don't walk."

"I see, but what is the reason for it?"

"She's slow in development."

"I see. And what is it that is responsible for her slow development?"

"It is the fact that she is mentally retarded."

"I see. And how do you know that she is mentally retarded?"

"Why you can see for yourself. She doesn't walk, she doesn't talk, she isn't toilet trained and doesn't do many other things like a mentally normal child" (Meyerson, Kerr, and Michael, 1967, pp. 224-225).

This quotation alludes to the tendency of diagnosticians to label behavior disorders as manifestations of a central pathology which often cannot be independently substantiated. Without some neurological or biochemical evidence to the contrary, the behavioral modifier prefers to deal with psychotherapy as a cluster of deviant behaviors, capable of removal by training efforts which shape the behaviors toward the normal range. That an abnormal behavior pattern can be deflected by reinforcement procedures is sometimes taken as *prima facie* evidence that that the abnormality was originally learned. In the case of childhood autism, an origin in reinforcement history has been speculatively traced out (Ferster, 1961).

Most psychologists see the processes of adaptation, psychotherapy, and child development in more complicated ways than they are envisaged in much of the rhetoric surrounding behavior modification. The early successes of the behavior modification efforts are quite provocative, but there are not yet the definitive successes which might serve as a kind of shield for the line of reasoning that lies behind them. The problems they seem to have definitely cleared up are minor, and one suspects a technology of behavior modification would not be needed to solve them. Patients with significant diagnostic entities have been benefited but not yet to a practical extent. Skepticism is still possible. Earlier applied efforts growing out of the experimental analysis movement have not yet had unequivocal success. Behavior shaping developed as a commercial animal training venture ultimately did not prove fully adequate to its proponents (Breland and Breland, 1961). Teaching machines and programmed learning have as yet only a tiny and uncertain place in the American educational system. Behavior modification must survive the period of early enthusiasm before its practical and theoretical weight can be felt.

That the movement may develop considerable theoretical significance seems likely. American inquiry into children's learning and cognitive processes has probably been a little too well-designed and well-controlled; the inquiry could use a clinical edge. The behavior modifiers and programmed learners have thrown open a window to the child in his natural confrontation with the issues of adap-

tation and education. Already, reading in the case protocols, one can find significant and provocative accounts of side effects of intervention, side effects more interesting than the reinforcement effect itself. In some of the intervention procedures themselves, one suspects that there are more agents than reinforcement schedules at work upon the subject, the focusing of his attention, the organization of his behavior over time, the reduction of stress—which might require more than the law of effect for their conceptualization. Behavior modification techniques might now represent new behavior for the experimental psychologist, behavior which is currently being reinforced, and one might reasonably expect that behavior in the terms of that discourse to eventuate in what others might call new thinking.

SOME SUMMARY COMMENTS

In this section, before turning to a consideration of the Russian form of stimulus-response analysis, it seems well to try to give some general perspective on the contemporary influence of the learning theory tradition. It must be said, again, that the problem of obtaining such a perspective is considerable. Within child psychology, one finds a series of outcroppings of the learning theory tradition, heterogeneous with respect to the amount and depth of the issues they address in the literature of child psychology, relatively more homogeneous in their conception of procedure, method, strategy, significant variables, terminology, and the nature of scientific development. The homogeneities lie in the diverse connections of the various efforts with the programs of Hull, Spence, and Skinner and, behind them historically, we find what seems to be the least common denominator of the group as a whole, the learning theory point of view, formed before the learning theories in the Behaviorism of the 1910s and 1920s.

For child psychologists at least, the tradition offers no articulated learning theory or even a theory of child development. It nevertheless has a "position" that is generally understood and, in the sloganizing way in which various theoretical positions are often seen to be in contention, it stands as a force against the geneticism of Piaget and Werner

in that it is usually seen as a debate which is insistent on environment, learning, reinforcement, and peripheralism, against others who contend for maturation, stages, development, and central structures as causative agents. The debating position is not imaginary, the characteristic arguments regularly flicker in the writings of the S-R proponents. But there is no one drawn-together statement of the position acceptable to all proponents. The only approximation to it is the pair of short books by Bijou and Baer (1961, 1965), but those two volumes would probably seriously misrepresent the S-Rism of Berlyne, of Bandura, and of the Kendlers.

Looked at more closely, the literature of the learning theory tradition reveals its diversity and within that diversity another, less recognized, pattern. The theoretical wing of the literature, largely descended from the Hull-Spence tradition, has less and less been preoccupied with the characteristic variables and system-building of that tradition, but has more and more drawn toward the edge of the behavioristic grounds. The basic research and systematization is building around issues of novelty, familiarization, attention, inference, strategy, and imitative learning. Those concerned with the experimental analysis of behavior have more and more moved toward interventive and applied efforts where, holding to the behavioristic view of affairs, they have nevertheless moved into ground which most psychologists would consider out of the reach of a purely behavioristic conception. The stimulus-response analysis holds the methodological ground it has generally always held in psychology, that of a conservative, behavioristically parsimonious physicalism though that ground become more difficult to hold as proponents are pulled with the general trend of psychology toward a new cognitivism, an interest in biological variables, and maturation.

The cause of this difficulty is of some interest. The general tendency and the natural tendency is to view the learning theory tradition as a general conception of human nature, and to consider its adequacy in that regard. Seeing the learning theory tradition in this way, one can recognize the force of certain devastating criticisms of the position which have regularly appeared recently, and one can anticipate the early demise of this

peculiarly shortsighted construction of the last generation of psychologists. Or, taking the longer view, one may recognize in the learning theories their descent from traditional Associationism, and one may see in their waning the cure of a much older obsession.

Associationism has been our only really general theory since we began to think about human behavior. It may be that in this complicated field we have stumbled upon the right answer at our first attempt, that somehow or another we already find ourselves in the alley leading to the food-box with only minor obstacles to surmount. The likelihood seems small, for the maze must be large. Alternatively we have been scrabbling for a century or two at the rather ill-defined end of a *cul-de-sac* whose entrance was rendered attractive in the eighteenth century by the rapid growth of classical physics and, above all, chemistry. History would support the latter alternative" (Drevel, 1968, p. 27).

The learning theory tradition is waning, and the arguments against it have considerable point, but one misses one point of discussion in the current round of post-mortems. Behaviorism and the learning theory tradition were descendants of associationism, but this was only an incidental fact of the thrust which lay behind their development. They were, or shortly became, general conceptions of human nature, but they did so in the face of exactly the same arguments at the turn of the century as those raised at the middle of the century. The ideological shortcomings of the learning theory tradition have been constant, and constantly recognized, and the rise and fall of the tradition may have to do with other issues—programmatic issues. There are two key questions that the learning theory tradition seems addressed to: (1) Can psychology become a self-contained science? (Can one find a way to build a behavior theory?) (2) Can psychology develop a cooperative and cumulative research tradition? In this view, the learning theory tradition failed to catch hold because the behavior theories did not manage to become self-propagating and self-organizing. The vast mass of learning literature lies, impossible to read and remember, beside the vast mass of other research findings which accumulates, largely unsynthesized, in

the back journals. If this view is correct, the originating questions that motivated the learning theory effort lie once more on the table.

There is no great urge to take the issues up. We have all become a little tired of methodology, of scientific prospect, of those seductive analogies between psychology and physics-seen-at-a-distance. To a greater extent than before, psychologists within and without the tradition are following their noses, less and less able or concerned to keep their ideological lines clear. The result is more scatter-shot and more interesting. The syntheses appear, but they are less planned, less predictable, more intuitive. Perhaps, aided and abetted by the learning theories, we have reached a more adequate plane of scientific discourse which is not, as expected, a level of all-embracing empiricism. Rather, that plane may be one where the intuition of the psychologist-at-large has been sophisticated, where method and modelling have their place, but where the interchange among diverse psychologists may take place usefully without a perfectly adequate intersubjective language, uniform body of methods, or spelled out program. One needs to take account of the psychology of science as well as the philosophy of science. When scientists communicate, they are not always exchanging facts and they do not always need a purified thing-language. They are often intercalibrating schemata and they may need a discourse replete with analogies, metaphors, and models to bring this about.

The preceding quotation from Dwyer may be modified slightly. There has always been a general theory opposed to Associationism which has been waiting in the wings of American psychology. It has been peculiarly at home in American developmental psychology, we speak here of the genetic-rationalist tradition outlined earlier. It is, one suspects, the viable alternative to the associationist tradition. To work meaningfully within the tradition, it has at least usually been the case that one must treat behavioral manifestations as an expression of sources not discernible within the observable realm, that one must move to a parsimony of comprehensive consistency rather than a parsimony of simplicity or seeableness. One must relinquish reliance on the single cause-single-effect conception of explanation. In short, one must relinquish a

great many of the guidelines to which American research practices have traditionally hewed closely.

RUSSIAN REFLEXOLOGY AND CHILD PSYCHOLOGY

The Russian treatment of stimulus-response psychology and the extension of that treatment to child psychology, offers a contrast to the American development of the tradition.

Americans are inclined to feel an amused kind of skepticism about Russian claims to have invented things first, but in the case of behaviorism there is some evidence suggesting that the Russians did, indeed, see the point first. The following quote is taken from I. M. Sechenov's *Reflexes of the Brain*, published in 1863, and represents an unmistakable assertion of the behavioristic thesis.

All the endless diversity of the external manifestations of the activity of the brain can be finally regarded as one phenomenon,—that of muscular movement. Be it a child laughing at the sight of toys, or Garibaldi smiling when he is persecuted for his excessive love for his fatherland, a girl tiembling at the first thought of love, or Newton enunciating universal laws and writing them on paper,—everywhere the final manifestation is muscular movement. In order to help the reader to reconcile himself with this thought more readily, I will remind him of the frame-work created by the mind of humanity to include all manifestations of brain activity, this frame-work is “*word and deed*.” Under *deed*, the popular mind conceives, without question, every external mechanical activity of man based exclusively on the use of muscles. And under *word*, as the educated reader will realize, is understood a certain combination of sounds produced in the larynx and the cavity of the mouth, again by means of muscular movements (Sechenov, 1863, p. 390).

Sechenov's anticipation of the behavioristic thesis seems something more than the chancy anticipations of all psychological points which one repeatedly finds in the literature and philosophy of earlier times. The thesis that one knows another man only by his behavior is, after all, not very far from common sense and it would be a distinct sur-

prise if it took mankind until the twentieth century to first see it and speak about it. Behaviorism was a "discovery" for psychologists only when and as it became a strong principle of organization of the inquiry process of the field, the point of the Sechenov "discovery" was that there seems every reason to believe that it was definitive and generative for the evolution of a line of Russian psychological endeavor. Sechenov's scheme for brain and mind was not very influential upon European psychological analysis—something very much like his scheme, promulgated by the British neurologist Hughlings Jackson did have influence—but his treatment was immensely popular in Russia, and it had direct and important influence on Ivan Pavlov (Babkin, 1949).

The behavioristic point was only incidental to Sechenov's psychophysiology, which sketched a grand design for the understanding of the interplay between mind and body (Yaroshevski, 1968). Pavlov, after him, seems to have accepted the design and begun its substantiation, to have placed it on an experimental format, and to have begun the process of working out the system in detail. The behavioristic thesis was a part of that design, and there is some evidence that it took Pavlov a little trouble to accept it, when he did, he did so vehemently (Pavlov, 1928). Pavlov's writings were the major point of contact between American Soviet psychology for a good many years, and it is only recently that the two national groups have again begun comparing notes. The evolution of conditioning in the Soviet Union has been quite different from its history here and consequently the impingement of the conditioning tradition upon child psychology has been quite different. A number of circumstances make this so.

Some recent surveys (Bauer, 1952, Mintz, 1958, O'Connor, 1961) enable us to get a perspective on the Russian discipline of psychology as a whole. These surveys, and the good number of direct translations of Russian work, give us some sense of a spectrum of psychological efforts organized quite differently from our own. One must envisage first a disciplinary line which comes between the conditioning tradition and psychology. Conditioning work has been considered to be a part of physiology, and is typically published in a different journal (*The Journal of Higher*

Nervous Activity) than work considered psychological (*Questions of Psychology*). This is not to imply that conditioning, and Pavlov, are not important sources for the Russian psychological work. They are not the only sources and, apparently, they have not been the centers of so strongly formed a programmatic movement as has developed in American psychology.

The status of psychology as a discipline has been politically touchy in the past decades. There were no psychological journals from 1935 to 1954. Sources disagree somewhat about just how contaminating political pressures have been upon Russian psychological efforts, but it seems that, at least superficially, Russian psychologists have had to be concerned about the compatibility of their work with dialectical materialism and their writings have showed some care to be politically progressive. Intelligence testing was officially forbidden by the Communist party in 1936. Dialectical materialism has been seen as incompatible with notions of the active unconscious, with materialism (the physicalistic positivism which has been influential in American psychology), and with extreme idealism, a pure phenomenology. Not necessarily for political reasons, the spectrum of Russian psychology as a discipline has failed to include good-sized components of our own psychoanalysis, social psychology, and industrial psychology.

There are thus differences in the political and professional matrix of forces in Soviet and American psychology and because of these differences comparisons need to be made with caution. Nevertheless, it is at least interesting to try to imagine the Russian development of S-R psychology as a kind of control for the American experience. Pavlovian conditioning was enormously influential upon Russian psychology, but it was never made the centerpiece of an effort at scientific and methodological reform of the discipline. There was no equivalent of the behavioristic revolution and consequently there seems now to be no equivalent of the cognitivist counterrevolution. Rather, elements of the prebehavioristic psychology have survived to the present day in Russia, coexisting with the development of conditioning methodology.

Textbooks of psychology typically define it as the science of mind or psyche. The interests

of researchers are directed toward consciousness and the analysis of the reflective processes by which it forms a judgment of experience and a guidance of voluntary behavior. Research on conditioning is not seen as incompatible with this.

The stress on consciousness and cognitive factors in behavior is not contradicted by the acceptance of the conditioned reflex as a basis of adaptive behavior. The conditional reflex is apt to be viewed not as a blindly functioning habit based on stimulus-response connections but as a flexible form of adjustment which enables the organism to respond to signals (Mintz, 1958, p. 497).

The more relaxed view of conditioning provokes a quite different treatment of it. Where in American psychology the stimulus has been made an undefined term in a calculus of learning and the S-R connection an undefined term in a calculus of higher-order behavior, the Russians have not logicized these terms. The stimulus is seen as the outcome of a process that requires explaining through conjoint behavioral and neuropsychological analysis.

The understanding of sensory (especially auditory) processes underwent a radical change as a result of the introduction of Pavlov's *reflex theory of sensation* and concept of *analyzers*. *Sensation incorporates the process of analysis and synthesis of signals while they are still in the first stages of arrival* (Luria, 1966a, p. 97).

Because the treatment of behaviorism and conditioning has not been seen as methodologically preemptive, those working with conditioning phenomena can coexist with other veins of research which are continuations of German introspectionism. The work of the Georgian group, a major sector of Russian activity, seems to be essentially an elaboration of the analysis of sets first begun by the Wurtzburg group (Uznadze, 1966, Natadze, 1961).

There are also, it might be said, some procedural effects of the fact that the Russians did not develop a methodological revolution. Russian papers do not as sharply separate philosophical and psychological issues, and research reports are not so scrupulous in separating findings from interpretation. Proce-

dures are not always so completely reported. Statistics are not a *sine qua non* in research work, and statistical regularities are accepted only when their implications can be shown to have some satisfactory bearing on an otherwise tenable line of explanation of the individual's behavior.

Given this kind of setting for the Russian treatment of the conditioning, the impingement of stimulus-response analysis upon child psychology is of an entirely different character in Russian work. It does not convey an insistence on parsimony or a resistance to explanations which appeal to central factors or hypothetical constructs. It is intrinsically more speculative since it is not so associated with the canons of testability and rigorous and comprehensive experimental proof. Carrying a much lighter methodological load, the analysis has traveled a useful distance into the issues which are now so central to the American behavior theory group—attention and reasoning.

At several levels, the Russians have been concerned with the subject's work with the stimulus as a precursor to his formation of an adaptation to it. At the level of conditioning, the Russians have identified an orienting reflex, a set of postural and autonomic reactions most typically identified by vasomotor components in finger and forehead, which is an important precursor and participant to the establishment of classical conditioning. The orienting reflex is presumed to be a forerunner of what one would usually call attention to the stimulus, and an elaborate experimental analysis of the reflex has led to the suggestion that it is reflective of the processes of neuronal modelling of the stimulus (Sokolov, 1963).

At a more motor level, orienting-investigatory behavior of the child has been envisaged as separate from and a precursor to the learning of voluntary motor patterns.

One could assume that preliminary orientation leads to formation of the habit itself and the formation of that system of connections which forms its basis. Our data, however, do not confirm this notion. What occurs is that, following the preliminary orientation, the motor system in the process of development appears not to have been assimilated yet and a number of additional motor exercises is needed before the habit is finally established.

Although getting somewhat ahead, we could say that, in the process of orientation, not the system of the performed motor reactions is formed but *the image*, under control of which the subsequent functioning of this system is made possible (Zaporozhets, 1965, p. 436)

A staged sequence of interaction between the orienting activity and the establishment of the motor pattern is found

1 There is a "chaotic" orientation pattern, widely distributed, as the child establishes initial familiarity with the task

2 The orienting reactions begin to be channelled toward those aspects of the situation which are relevant to the task, and there seem to be strategic connections or anticipation involving one and another. A system of orientation is formed

3 With the establishment of the motor learning, the motor and external verbal reactions associated with the orienting system diminish, are inhibited, and they form an image which, in effect, exists as a schema of the voluntary behavior

4 If, finally, the now correctly executed adaptive reaction is repeated again and again, it becomes stereotyped and automatized, and there is an extinction of most orienting reactions. The extinction is not complete and, for example, agents offering reinforcement continue to elicit orienting (Zaporozhets, 1961, 1965)

At the level of the conditioned reflex, and at the level of voluntary behavior, an orienting process is seen as a precursor to adaptation and as an index to the formation of an adequate central representation of the relevant environment—in the case of voluntary behavior, part and parcel of the forming of the representation. In addition, several interesting development trends have been acknowledged. The habituation of initial orientation is more rapid as children grow older and, in several ways, seems indicative of "higher" or more intact functioning (Lynn, 1966). During the preschool era, the orienting-investigatory activity of the child is seen to show a developmental move from motor-tactile to visual exploration (Zaporozhets, 1961).

A connected vein of Russian investigation

has examined the directing or regulating functions which language exerts upon behavior. The relevant research by Luria (1961) and Vygotsky (1962) is the best-known Russian work to American child psychologists. Just as the line of research previously discussed traces the internalization of movement and visualization patterns to become cognitive representations of the situation and directors of adaptive activity, so here the directive functions of language are traced ontogenetically. Luria traces the initial influence of language, in the younger years, first as an excitatory influence, later as both excitatory and inhibitory, finally as regulative and directive. Vygotsky traces this regulatory language as it is used by the young child to explicitly direct himself and then, subsequently, as it internalizes to become an organ of planning and reasoning.

All this has some similarity to the American conception of mediation as the basis for abstract thought processes. Indeed, the Russian conception is a somewhat looser and broader version of the behavior theory conception of mediation. They are different elaborations, perhaps, of Pavlov's initial suggestion that human higher mental processes should be conceived of as a "second signal system."

On the whole, this parallelism between the Russian child psychology and the American learning theory tradition is misleading if it is taken as a sign that these two traditions differ in degree rather than in kind. The Russian tradition is quite willing to work with judicious mentalizing and neurologizing—in fact, sees the ultimate understanding of psychological data to lie in the understanding of consciousness through the synthesis of behavioral and neurological information. There is not acceptance of the learning theory point of view. Nevertheless, the Russian work can be seen as supporting and extending the present cognitivist trends within the behavior theory group. Their work has already been interjected in significant ways because of its considerable influence on Berlyne's neobehavioristic formulations (Berlyne, 1960, 1965). It is exactly with respect to the issues addressed in those volumes, attention and reasoning, that the Russians have established an experimental foothold while the grasp of behavior theory is still not secure.

9. Piaget's Theory¹

JEAN PIAGET²

The following theory of development, which is particularly concerned with the development of cognitive functions, is impossible to understand if one does not begin by analyzing in detail the biological presuppositions from which it stems and the epistemological consequences in which it ends. Indeed, the fundamental postulate that is the basis of the ideas summarized here is that the same problems and the same types of explanations can be found in the three following processes:

a) The adaptation of an organism to its environment during its growth, together with the interactions and autoregulations which characterize the development of the "epigenetic system" (Epigenesis in its embryological sense is always determined both internally and externally.)

b) The adaptation of intelligence in the course of the construction of its own structures,

which depends as much on progressive internal coordinations as on information acquired through experience.

c) The establishment of cognitive or, more generally, epistemological relations, which consist neither of a simple copy of external objects nor of a mere unfolding of structures preformed inside the subject, but rather involve a set of structures progressively constructed by continuous interaction between the subject and the external world.

We begin with the last point, on which our theory is furthest removed both from the ideas of the majority of psychologists and from "common sense."

I THE RELATION BETWEEN SUBJECT AND OBJECT

I In the common view, the external world is entirely separate from the subject, although it encloses the subject's own body. Any objective knowledge, then, appears to be simply the result of a set of perceptive recordings, motor associations, verbal descriptions, and the like, which all participate in producing a sort of figurative copy or "functional copy" (in Hull's terminology) of objects and the connections between them. The only function of intelligence is systematically to file, correct, etc., these various sets of information, in this process, the more faithful the critical copies, the more consistent the final system will be. In such an empiricist prospect, the content of intelligence comes from outside, and the coordinations that organize it are only the consequences of language and symbolic instruments.

¹ This chapter was written in French and translated by Dr. Guy Gellerier of the University of Geneva and Professor Jonas Langer of the University of California at Berkeley. We are also grateful to Professors Barbel Inhelder and Hermione Sinclair for their assistance in the translation.

² The present chapter is, in part, the expansion of an article on my conceptions of development published in *Journal International de Psychologie*, a summary of previous publications, but it also takes into account recent or still unpublished work by the author or his collaborators and colleagues. As a matter of fact, "Piaget's theory" is not completed at this date and the author of these pages has always considered himself one of the chief "revisionists of Piaget" (Author's note).

But this passive interpretation of the act of knowledge is in fact contradicted at all levels of development and, particularly, at the sensorimotor and prelinguistic levels of cognitive adaptation and intelligence. Actually, in order to know objects, the subject must act upon them, and therefore transform them: he must displace, connect, combine, take apart, and reassemble them.

From the most elementary sensorimotor actions (such as pushing and pulling) to the most sophisticated intellectual operations, which are interiorized actions, carried out mentally (e.g., joining together, putting in order, putting into one-to-one correspondence), knowledge is constantly linked with actions or operations, that is, with *transformations*.

Hence the limit between subject and objects is in no way determined beforehand, and, what is more important, it is not stable. Indeed, in every action the subject and the objects are fused. The subject needs objective information to become aware of his own actions, of course, but he also needs many subjective components. Without long practice or the construction of refined instruments of analysis and coordination, it will be impossible for him to know what belongs to the object, what belongs to himself as an active subject, and what belongs to the action itself taken as the transformation of an initial state into a final one. Knowledge, then, at its origin, neither arises from objects nor from the subject, but from interactions—at first inextricable—between the subject and those objects.

Even these primitive interactions are so close-knit and inextricable that, as J. M. Baldwin noted, the mental attitudes of the infant are probably "adualistical." This means they lack any differentiation between an external world, which would be composed of objects independent of the subject, and an internal or subjective world.

Therefore the problem of knowledge, the so-called epistemological problem, cannot be considered separately from the problem of the development of intelligence. It reduces to analyzing how the subject becomes progressively able to know objects adequately, that is, how he becomes capable of objectivity. Indeed, objectivity is in no way an initial property, as the empiricists would have it,

and its conquest involves a series of successive constructs which approximate it more and more closely.

2 This leads us to a second idea central to the theory, that of *construction*, which is the natural consequence of the interactions we have just mentioned. Since objective knowledge is not acquired by a mere recording of external information but has its origin in interactions between the subject and objects, it necessarily implies two types of activity—on the one hand, the coordination of actions themselves, and on the other, the introduction of interrelations between the objects. These two activities are interdependent because it is only through action that these relations originate. It follows that objective knowledge is always subordinate to certain structures of action. But those structures are the result of a *construction* and are not given in the objects, since they are dependent on action, nor in the subject, since the subject must learn how to coordinate his actions (which are not generally hereditarily programmed except in the case of reflexes or instincts).

An early example of these constructions (which begin as early as the first year) is the one that enables the 9- to 12-month-old child to discover the permanence of objects, initially relying on their position in his perceptual field, and later independent of any actual perception. During the first months of existence, there are no permanent objects, but only perceptual pictures which appear, dissolve, and sometimes reappear. The "permanence" of an object begins with the action of looking for it when it has disappeared at a certain point A of the visual field (for instance, if a part of the object remains visible, or if it makes a bump under a cloth). But, when the object later disappears at B, it often happens that the child will look for it again at A. This very instructive behavior supplies evidence for the existence of the primitive interactions between the subject and the object which we mentioned (§ 1). At this stage, the child still believes that objects depend on this action and that, where an action has succeeded a first time, it must succeed again. One real example is an 11-month-old child who was playing with a ball. He had previously retrieved it from under an armchair when it had rolled there before. A moment

later, the ball went under a low sofa. He could not find it under this sofa, so he came back to the other part of the room and looked for it under the armchair, where this course of action had already been successful.

For the scheme³ of a permanent object that does not depend on the subject's own actions to become established, a new structure has to be constructed. This is the structure of the "group of translations" in the geometrical sense: (a) the translation $AB + BC = AC$, (b) the translations $AB + BA = O$, (c) $AB + O = AB$, (d) $AC + CD = AB + BD$. The psychological equivalent of this group is the possibility of behaviors that involve returning to an initial position or detouring around an obstacle (a and d). As soon as this organization is achieved—and it is not at all given at the beginning of development, but must be constructed by a succession of new coordinations—an objective structuration of the movements of the object and of those of the subject's own body becomes possible. The object becomes an independent entity, whose position can be traced as a function of its translations and successive positions. At this juncture the subject's body, instead of being considered the center of the world, becomes an object like any other, the translations and positions of which are correlative to those of the objects themselves.

The group of translations is an instance of the construction of a structure, attributable simultaneously to progressive coordination of the subject's actions and to information provided by physical experience, which finally constitutes a fundamental instrument for the organization of the external world. It is also a cognitive instrument so important that it

³ Throughout this paper the term *scheme* (plural, *schemes*) is used to refer to *operational* activities, whereas *schema* (plural, *schemata*) refers to the figurative aspects of thought—attempts to represent reality without attempting to transform it (imagery, perception and memory). Later in this paper the author says, "images, however schematic, are not schemes. We shall therefore use the term *schemata* to designate them. A *schema* is a simplified image (e.g., the map of a town), whereas a *scheme* represents what can be repeated and generalized in an action (for example the scheme is what is common in the actions of 'pushing' an object with a stick or any other instrument)."

contributes to the veritable "Copernican revolution" babies accomplish in 12 to 18 months. Whereas before he had evolved this new structure the child would consider himself (unconsciously) the motionless center of the universe, he becomes, because of this organization of permanent objects and space (which entails moreover a parallel organization of temporal sequences and causality), only one particular member of the set of the other mobile objects which compose his universe.

3. We can now see that even in the study of the infant at sensorimotor levels it is not possible to follow a psychogenetic line of research without evolving an implicit epistemology, which is also genetic, but which raises all the main issues in the theory of knowledge. Thus the construction of the group of translations obviously involves physical experience and empirical information. But it also involves more, since it also depends on the coordinations of the subject's action. These coordinations are not a product of experience only, but are also controlled by factors such as maturation and voluntary exercise, and, what is more important, by continuous and active autoregulation. The main point in a theory of development is not to neglect the activities of the subject, in the epistemological sense of the term. This is even more essential in this latter sense because the epistemological sense has a deep biological significance. The living organism itself is not a mere mirror image of the properties of its environment. It evolves a *structure* which is constructed step by step in the course of epigenesis and which is not entirely preformed.

What is already true for the sensorimotor stage appears again in all stages of development and in scientific thought itself but at levels in which the primitive actions have been transformed into *operations*. These operations are interiorized actions (e.g., addition which can be performed either physically or mentally) that are reversible (addition acquires an inverse in subtraction) and constitute set-theoretical structures (such as the logical additive "grouping" or algebraic groups).

A striking instance of these operational structurings dependent on the subject's activity, which often occurs even before an

experimental method has been evolved, is *atomism*, invented by the Greeks long before it could be justified experimentally. The same process can be observed in the child between 4 to 5 and 11 to 12 years of age in a situation where it is obvious that experience is not sufficient to explain the emergence of the structure and that its construction implies an additive composition dependent on the activities of the subject. The experiment involves the dissolution of lumps of sugar in a glass of water. The child can be questioned about the conservation of the matter dissolved and about the conservation of its weight and volume. Before age 7 to 8 the dissolved sugar is presumed destroyed and its taste vanished. Around this age sugar is considered as preserving its substance in the form of very small and invisible grains, but it has neither weight nor volume. At age 9 to 10 each grain keeps its weight and the sum of all these elementary weights is equivalent to the weight of the sugar itself before dissolution. At age 11 to 12 this applies to volume (the child predicts that after the sugar has melted, the level of the water in the container will remain at its same initial height).

We can now see that this spontaneous atomism, although it is suggested by the visible grains becoming gradually smaller during their dissolution, goes far beyond what can be seen by the subject and involves a step-by-step construction correlative to that of additive operations. We thus have a new instance of the origin of knowledge lying neither in the object alone nor in the subject, but rather in an inextricable interaction between both of them, such that what is given physically is integrated in a logicomathematical structure involving the coordination of the subject's actions. The decomposition of a whole into its parts (invisible here) and the recomposition of these parts into a whole are in fact the result of logical or logicomathematical constructions and not only of physical experiments. The whole considered here is not a perceptual "Gestalt" (whose character is precisely that of *nonadditive* composition, as Kohler rightly insisted) but a sum (additive), and as such it is produced by operations and not by observations.

4 There can be no theoretical discontinuity between thought as it appears in children and adult scientific thinking, this is the reason

for our extension of developmental psychology to genetic epistemology. This is particularly clear in the field of logicomathematical structures considered in themselves and not (as in ¶ 2 and ¶ 3) as instruments for the structuration of physical data. These structures essentially involve relations of inclusion, order, and correspondence. Such relations are certainly of biological origin, for they already exist in the genetic (DNA) programming of embryological development as well as in the physiological organization of the mature organism before they appear and are reconstructed at the different levels of behavior itself. They then become fundamental structures of behavior and of intelligence in its very early development before they appear in the field of spontaneous thought and later of reflection. They provide the foundations of these progressively more abstract axiomatizations we call logic and mathematics. Indeed, if logic and mathematics are so-called "abstract" sciences, the psychologist must ask: Abstracted from what? We have seen their origin is not in objects alone. It lies, in small part only, in language, but language itself is a construct of intelligence. Chomsky even ascribes it to innate intellectual structures. Therefore the origin of these logicomathematical structures should be sought in the activities of the subject, that is, in the most general forms of coordinations of his actions, and, finally, in his organic structures themselves. This is the reason why there are fundamental relations among the biological theory of adaptation by self-regulation, developmental psychology, and genetic epistemology. This relation is so fundamental that if it is overlooked, no general theory of the development of intelligence can be established.

II ASSIMILATION AND ACCOMMODATION

5 The psychological meaning of our previous points (¶ 1 to 4) is that the fundamental psychogenetic connections generated in the course of development cannot be considered as reducible to empirical "associations"; rather, they consist of *assimilations*, both in the biological and intellectual sense.

From a biological point of view, assimilation is the integration of external elements into evolving or completed structures of an

organism In its usual connotation, the assimilation of food consists of a chemical transformation that incorporates it into the substance of the organism Chlorophyllian assimilation consists of the integration of radiation energy in the metabolic cycle of a plant Waddington's "genetic assimilation" consists of a hereditary fixation by selection on phenotypes (phenotypic variations being regarded, in this case, as the genetic system's "answer" to stresses produced by the environment) Thus all the organism's reactions involve an assimilation process which can be represented in symbolic form as follows

$$(T + I) \rightarrow AT + E \quad (1)$$

where T is a structure, I the integrated substances or energies, E the eliminated substances or energies, and A a coefficient > 1 expressing the strengthening of this structure in the form of an increase of material or of efficiency in operation⁴ Put in this form it becomes obvious that the general concept of assimilation also applies to behavior and not only to organic life Indeed, no behavior, even if it is new to the individual, constitutes an absolute beginning It is always grafted onto previous schemes and therefore amounts to assimilating new elements to already constructed structures (innate, as reflexes are, or previously acquired) Even Harlow's "stimulus hunger" cannot be reduced simply to subordination to the environment but must rather be interpreted as a search for "functional input" ("éléments fonctionnels") that can be assimilated to the schemes or structures actually providing the responses

At this point it is appropriate to note how

⁴For example, take T to be an already established classification on a set of objects, O , which divides it into two distinct subclasses I is a set of new objects that are added to the original ones and to which the classification T must be extended When this is done (I has been assimilated to T), it turns out that there are say two new subclasses (the whole structure is now AT) and some properties of the new objects I (e.g., the number of elements in I , or their shape, size or color) have been neglected in the process We now have $T + I \rightarrow AT + E$, where T = the two original subclasses, I = the new elements, AT = the four subclasses, and E = the irrelevant properties of the new elements, that is, the properties which are not used as criteria for classifying in this specific instance

inadequate the well known "stimulus-response" theory appears in this context, as a general formulation of behavior It is obvious that a stimulus can elicit a response only if the organism is first sensitized to this stimulus (or possesses the necessary reactive "competence" as Waddington characterizes genetic sensitization to specific inducers)

When we say an organism or a subject is sensitized to a stimulus and able to make a response to it, we imply it already possesses a scheme or a structure to which this stimulus is assimilated (in the sense of incorporated or integrated, as defined previously) This scheme consists precisely of a capacity to respond Hence the original stimulus-response scheme should not have been written in the unilateral $S \rightarrow R$ form, but in the form

$$S \nrightarrow R \quad \text{or} \quad S \rightarrow (AT) \rightarrow R \quad (2)$$

where AT is the assimilation of the stimulus S to the structure T

We thus return to the equation $T + I \rightarrow AT + E$ where, in this case, T is the structure, I the stimulus, AT the result of the assimilation of I to T , that is the response to the stimulus, and E is whatever in the stimulus situation is excluded in the structure

6 If assimilation alone were involved in development, there would be no variations in the child's structures Therefore he would not acquire new content and would not develop further Assimilation is necessary in that it assures the continuity of structures and the integration of new elements to these structures Without it an organism would be in a similar situation to that of chemical compounds, A , B , which, in interaction, give rise to new compounds C and D (The equation would then be $A + B \rightarrow C + D$ and not $T \rightarrow AT$)

Biological assimilation itself, however, is never present without its counterpart, accommodation During its embryological development, for instance, a phenotype assimilates the substances necessary to the conservation of its structures as specified by its genotype But, depending on whether these substances are plentiful or rare or whether the usual substances are replaced by other slightly different ones, nonhereditary variations (often called "accommodates") such as changes in shape or height may occur These variations are specific to some external conditions Simi-

larly, in the field of behavior we shall call accommodation any modification of an assimilatory scheme or structure by the elements it assimilates. For example, the infant who assimilates his thumb to the sucking schema will, when sucking his thumb make different movements from those he uses in suckling his mother's breast. Similarly, an 8-year-old who is assimilating the dissolution of sugar in water to the notion that substance is conserved must make accommodations to invisible particles different from those he would make if they were still visible.

Hence cognitive adaptation, like its biological counterpart, consists of an equilibrium between assimilation and accommodation. As has just been shown, there is no assimilation without accommodation. But we must strongly emphasize the fact that accommodation does not exist without simultaneous assimilation either. From a biological point of view, this fact is verified by the existence of what modern geneticists call "reaction norms"—a genotype may offer a more or less broad range of possible accommodations, but all of them are within a certain statistically defined "norm." In the same way, cognitively speaking, the subject is capable of various accommodations, but only within certain limits imposed by the necessity of preserving the corresponding assimilatory structure. In Eq 1 the term A in AT specifies precisely this limitation on accommodations.

The concept of "association," which the various forms of associationism from Hume to Pavlov and Hull have used and abused, has thus only been obtained by artificially isolating one part of the general process defined by the equilibrium between assimilation and accommodation. Pavlov's dog is said to associate a sound to food, which elicits its salivation reflex. If, however, the sound is never again followed by food, the conditioned response, or temporary link, will disappear, it has no intrinsic stability. The conditioning persists as a function of the need for food, that is, it persists only if it is part of an assimilatory scheme and its satisfaction, hence of a certain accommodation to the situation. In fact, an "association" is always accompanied by an assimilation to previous structures, and this is a first factor that must not be overlooked. On the other hand, insofar as the "association" incorporates some new in-

formation, this represents an active accommodation and not a mere passive recording. This accommodatory activity, which is dependent on the assimilation scheme is a second necessary factor that must not be neglected.

7 If accommodation and assimilation are present in all activity, their ratio may vary, and only the more or less stable equilibrium which may exist between them (though it is always mobile) characterizes a complete act of intelligence.

When assimilation outweighs accommodation (i.e., when the characteristics of the object are not taken into account except insofar as they are consistent with the subject's momentary interests) thought evolves in an egocentric or even autistic direction. The most common form of this situation in the play of the child is the "symbolic games" or fiction games, in which objects at his command are used only to represent what is imagined.⁵ This form of game which is most

⁵ The categories of play defined by Piaget (in *Play, Dreams and Imitation*, 1951, for example) are the following:

a Exercise Games These consist of any behavior without new structuration but with a new functional finality. For example, the repetition of an action such as swinging an object, if its aim is to understand or to practice the movement, is *not* a game. But the same behavior, if its aim is functional pleasure, pleasure in the activity in itself, or the pleasure of "causing" some phenomenon, becomes a game. Examples of this are the vocalizations of infants and the games of adults with a new car, radio, etc.

b Symbolic games These consist of behaviors with a new structuration, that of representing realities that are out of the present perceptual field. Examples are the fiction games where the child enacts a meal with pebbles standing for bread, grass for vegetables, etc. The symbols used here are individual and specific to each child.

c Rule Games These are behaviors with a new structuration involving the intervention of more than one person. The rules of this new structure are defined by social interaction. This type of game ranges over the whole scale of activities, starting with simple sensorimotor games with set rules (the many varieties of marble games, for instance) and ending with abstract games like chess. The symbols here are stabilized by convention and can become purely arbitrary in the more abstract games. That is, they bear no more relation (analogy) with what they represent. (Translator's note)

frequent at the beginning of representation (between 1½ and 3 years of age), then evolves toward constructive games in which accommodation to objects becomes more and more precise until there is no longer any difference between play and spontaneous cognitive or instrumental activities.

Conversely, when accommodation prevails over assimilation to the point where it faithfully reproduces the forms and movements of the objects or persons which are its models at that time, representation (and the sensorimotor behaviors which are its precursors and which also give rise to exercise games that develop much earlier than symbolic games) evolves in the direction of imitation. Imitation through action, an accommodation to models that are present, gradually extends to deferred imitation and finally to interiorized imitation. In this last form it constitutes the origin of mental imagery and of the figurative as opposed to the operative aspects of thought.

But as long as assimilation and accommodation are in equilibrium (i.e., insofar as assimilation is still subordinate to the properties of the objects, or, in other words, subordinate to the situation with the accommodations it entails, and accommodation itself is subordinate to the already existing structures to which the situation must be assimilated) we can speak of cognitive behavior as opposed to play, imitation, or mental imagery, and we are back in the proper domain of intelligence. But this fundamental equilibrium between assimilation and accommodation is more or less difficult to attain and to maintain depending on the level of intellectual development and the new problems encountered. However, such an equilibrium exists at all levels, in the early development of intelligence in the child as well as in scientific thought.

It is obvious that any physical or biological theory assimilates objective phenomena to a restricted number of models which are not drawn exclusively from these phenomena. These models involve in addition a certain number of logicomathematical coordinations that are the operational activities of the subject himself. It would be very superficial to reduce these coordinations to a mere "language" (though this is the position of logical positivism) because, properly speaking, they

are an instrument for structuration. For example, Poincaré narrowly missed discovering relativity because he thought there was no difference between expressing (or translating) phenomena in the "language" of Euclidean or of Riemannian geometry. Einstein was able to construct his theory by using Riemannian space as an instrument of *structuration*, to "understand" the relations between space, speed, and time. If physics proceeds by assimilating reality to logicomathematical models, then it must unceasingly accommodate them to new experimental results. It cannot dispense with accommodation because its models would then remain subjective and arbitrary. However, every new accommodation is conditioned by existing assimilations. The significance of an experiment does not derive from a mere perceptive recording (the "*Protokollsätze*" of the first "logical empiricists"), it cannot be dissociated from an *interpretation*.

8. In the development of intelligence in the child, there are many types of equilibrium between assimilation and accommodation that vary with the levels of development and the problems to be solved. At sensorimotor levels (before 1½ to 2 years of age) these are only practical problems involving immediate space, and as early as the second year, sensorimotor intelligence reaches a remarkable state of equilibrium (e.g., instrumental behaviors, group of displacements, see ¶ 2). But this equilibrium is difficult to attain, because during the first months, the infant's universe is centered on his own body and actions, and because of distortions due to assimilation not yet balanced by adequate accommodations.

The beginning of thought creates multiple problems of representation (which must extend to distant space and can no longer be restricted to near space) as well as the problem of adaptation no longer measured by practical success alone, thus intelligence goes through a new phase of assimilatory distortion. This is because objects and events are assimilated to the subject's own action and viewpoint and possible accommodations still consist only of fixations on figural aspects of reality (hence on states as opposed to transformations). For these two reasons—egocentric assimilation and incomplete accommodation—equilibrium is not reached. On the

other hand, from the age of 7 to 8 the emergence of reversible operations ensures a stable harmony between assimilation and accommodation since both can now act on transformations as well as on states.

Generally speaking, this progressive equilibrium between assimilation and accommodation is an instance of a fundamental process in cognitive development which can be expressed in terms of centration and decenteration. The systematically distorting assimilations of sensorimotor or initial representative stages, which distort because they are not accompanied by adequate accommodations, mean that the subject remains centered on his own actions and his own viewpoint. On the other hand, the gradually emerging equilibrium between assimilation and accommodation is the result of successive decenterations, which make it possible for the subject to take the points of view of other subjects or objects themselves. We formerly described this process merely in terms of egocentrism and socialization. But it is far more general and more fundamental to knowledge in all its forms. For cognitive progress is not only assimilation of information, it entails a systematic decenteration process which is a necessary condition of objectivity itself.

III THE THEORY OF STAGES

9. We have seen that there exist structures which belong only to the subject (§1), that they are built (§2), and that this is a step-by-step process (§7). We must therefore conclude there exist stages of development. Even authors who agree with this idea may use different criteria and interpretations of stage development. It therefore becomes a problem that requires discussion in its own right. The Freudian stages, for instance, are only distinct from each other in that they differ in one dominant character (oral, anal, etc.) but this character is also present in the previous—or following—stages, so that its “dominance” may well remain arbitrary. Gesell's stages are based on the hypothesis of the quasi-exclusive role of maturation, so that they guarantee a constant order of succession but may neglect the factor of progressive construction. To characterize the stages of cognitive development we therefore need to integrate two necessary conditions without

introducing any contradictions. These conditions for stages are (a) that they must be defined to guarantee a constant order of succession, and (b) that the definition allow for progressive construction without entailing total preformation. These two conditions are necessary because knowledge obviously involves learning by experience, which means an external contribution in addition to that involving internal structures, and the structures seem to evolve in a way that is not entirely predetermined.

The problem of stages in developmental psychology is analogous to that of stages in embryogenesis. The question that arises in this field is also that of making allowance for both genetic preformation and an eventual “epigenesis” in the sense of construction by interactions between the genome and the environment. It is for this reason that Waddington introduces the concept of “epigenetic system” and also a distinction between the genotype and the “epigenotype.” The main characteristics of such an epigenetic development are not only the well-known and obvious ones of succession in sequential order and of progressive integration (segmentation followed by determination controlled by specific “competence” and finally “integration”) but also some less obvious ones pointed out by Waddington. These are the existence of “creodes,” or necessary developmental sequences, each with its own “time tally,” or schedule, and the intervention of a sort of evolutionary regulation, or “homeorhesis.” Homeorhesis acts in such a way that if an external influence causes the developing organism to deviate from one of its creodes, there ensues a homeorhetical reaction, which tends to channel it back to the normal sequence or, if this fails, switches it to a new creode as similar as possible to the original one.

Each of the preceding characteristics can be observed in cognitive development if we carefully differentiate the construction of the structures themselves and the acquisition of specific procedures through learning (e.g., learning to read at one age rather than another). The question will naturally be whether development can be reduced to an addition of procedures learned one by one or whether learning itself depends on developmental laws which are autonomous.

This question can only be answered experimentally, but we shall discuss it further in Section IV. Whatever the answer is, it remains possible to distinguish between major structures, such as the operational "grouping," and particular acquisitions. It then becomes proper to inquire whether the construction of these major structures can be defined in terms of stages. If this were so, it would then become possible to determine their relations to developmental laws of learning.

10 If we restrict ourselves to major structures, it is strikingly obvious that cognitive stages have a sequential property, that is, they appear in a fixed order of succession because each one of them is necessary for the formation of the following one.

If we now consider only the principal periods of development, one can enumerate three of them:

a A sensorimotor period lasts until approximately 1½ years of age with a first subperiod of centration on the subject's own body (lasting about 7 to 9 months) followed by a second one of objectivization and spatialization of the schemes of practical intelligence.

b A period of representative intelligence leads to concrete operations (classes, relations, and numbers bound to objects) with a first preoperational subperiod (there is no reversibility or conservation, but the beginnings of directional functions and qualitative identities), which begins around 1½ to 2 years of age with the formation of semiotic processes such as language and mental imagery. This is followed by a second subperiod (at about 7 to 8 years) characterized by the beginnings of operational groupings in their various concrete forms and with their various types of conservation.

c Finally, there is the period of propositional or formal operations. This also begins with a subperiod of organization (11 to 13 years old) and is followed by a subperiod of achievement of the general combinatorial and the group INRC of the two kinds of reversibilities. (See ¶ 28 and fn 9.)

If we now consider the preceding sequence, it is easy to observe that each one of these periods or subperiods is necessary to the constitution of its successor. As a first example, why do language and the semiotic function

emerge only at the end of a long sensorimotor period where the only significates are indexes and signals, and where there are no symbols or signs? (If the acquisition of language were only dependent on an accumulation of associations, as is sometimes claimed, then it could occur much earlier⁶.) It has been shown that the acquisition of language requires that at least two conditions be satisfied. First, there must exist a general context of imitation allowing for interpersonal exchange, and second, the diverse structural characters which constitute the one basic unit of Chomsky's (1957) transformational grammars must be present. For the first of these conditions to be met means that in addition to the motor techniques of imitation (and this is by no means an easy task) the object, spatiotemporal, and causal decentrations of the second sensorimotor subperiod must have been mastered. For the second requirement, our collaborator H. Sinclair, who specializes in psycholinguistics, has shown (in her recent work which will shortly be published) that Chomsky's transformational structures are facilitated by the previous operation of the sensorimotor schemes, and thus that their origin is neither in an innate neurophysiological program (as Chomsky himself would have it) nor in an operant or other conditioning "learning" process [as Chomsky (1959) has shown conclusively].

A second example of the sequential character of our periods and subperiods is the subperiod of ages 2 to 7, which itself results from the sensorimotor schemes elaborated in

⁶ The contention is that there already exists symbol manipulation, that is, storage and computation, on indexes and signals during the sensorimotor stage. Therefore the absence of language cannot be attributed to the lack of such functions, and conditioning (classical or operant) should be possible at least on the input side. At this stage the child can discriminate between sounds and he should be able to respond selectively, verbally or otherwise, to phonetic inputs on a purely associative basis. It is claimed that this is impossible for more than a finite (and very limited) set of inputs because of the absence of the most essential linguistic structure (monoid) which would permit the generation and storage of rules allowing for the analysis and recognition of an unlimited set of organized sequences of sounds. (Translator's note.)

the ninth and tenth months and which prepares the concrete operations of ages 7 to 10. This subperiod is characterized by some negative aspects (lack of reversibility and absence of the concept of conservation), but it also evolves some positive achievements such as the directional functions [*fonctions orientées*—mappings where $y = f(x)$ with unity of the value $f(x)$ for any (x) and the qualitative identity $a = a$]. In fact, these functions already play an extensive role in preoperational thought. Then one-way orientation explains the general primacy of the concept of order at this level, with its adequate aspects, but this also is the source of systematic distortions (e.g., “longer” understood as “going farther”, estimation of a quantity of water by taking only its level into account). The elementary functions are nothing other than the connections inherent in the schemes of action (which, before they become operational, are always oriented toward a goal) and therefore originate in the sensorimotor schemes themselves. Qualitative identity (the type of identity expressed by the child when he says “It is the same water,” even if the quantity of water changes) has its origin in the concept of permanent object, and in the notion that the subject’s own body (as well as those of other subjects) maintains its identity both in time and in space, and these are three achievements of the sensorimotor stage. On the other hand, the one-way, directional functions and the identities they involve constitute the necessary condition for future operations. Thus we can see that the stages between 2 and 7 years are simultaneously an extension of the sensorimotor stages and the basis of the future concrete operations.

The propositional operations that appear between ages 11 and 15 with the INRC group and general combinatorial structures, all consist of applying operations to operations and transformations to transformations. It is therefore obvious that the existence of this last stage necessarily involves the acquisitions of the previous one (concrete operations, or operations to the first power).

11. Thus defined, the stages always appear in the same order of succession. This might lead us to assume that some biological factor such as maturation is at work. But it is certainly not comparable to the hereditary

neuropsychological programming of instincts. Biological maturation does nothing more than open the way to possible constructions (or explain transient impossibilities). It remains for the subject to actualize them. This actualization, when it is regular, obeys the law of creodes, that is, of constant and necessary progress such that the endogenous reactions find support in the environment and in experience. It would therefore be a mistake to consider the succession of these stages as the result of an innate predetermination, because there is a continual construction of novelty during the whole sequence.

The two best proofs of this last point are the possibilities of deviations from the norm (with regulation by homeorhesis) and of variations in the time tally with the possibility of accelerations or delays. Deviations may be brought about by unforeseen experiences encountered by the activity of the child himself as well as by adult pedagogical interventions. Some pedagogical interventions can, of course, accelerate and complete spontaneous development, but they cannot change the order of the constructions. For example, educational programs might introduce the concept of metric proportions a long time after the elementary arithmetical operations, although a proportion seems to consist only of an equivalence between two divisions, as in $4 : 2 = 6 : 3$. But there also exist untimely pedagogical interventions, such as those of parents who teach their children to count up to 20 or 50 before they can have any concept of number. In many cases, such premature acquisitions in no way affect the creode specific to the construction of integers. For instance, when two lines of m and n elements ($m = n$), respectively, are first put into visual one-to-one correspondence and their lengths changed by changing the spacing of the elements, the fact that the child of a certain age can count will not prevent him from saying that the longer line has more elements. On the other hand, when a pedagogical intervention has been successful or when the child obtains by himself a partial conquest in a specific operatory domain, the problem of the interactions between the various creodes remains still unsolved. In the case of classes or relations, for example, are the additive and multiplicative operations always synchronic—as they often seem to be—or can

one follow the other, and in that event does the final synthesis remain unchanged (as is probably the case)?

12 In considering the problem of duration or rate of succession of the stages, we can readily observe that accelerations or delays in the average chronological age of performance, depend on specific environments (e.g., abundance or scarcity of possible activities and spontaneous experiences, educational or cultural environment) but the order of succession will remain constant. Some authors even believe unbounded acceleration would be possible and desirable. Bruner (1960) went so far as to assert that if one tackles it the right way, one can teach anything to children of any age, but he does not seem to believe this any longer. On this point, however, we can quote two situations investigated by Gruber. The first is that of developing kittens. It has been shown that they go through the same stages as infants in acquiring the "concept" of permanent object, and further that they achieve in 3 months what the infant does in 9. However, they do not progress any further and one may wonder whether the child's slower rate of development does not, in this case, make for greater progress ultimately. The second study by Gruber concerns the remarkable tardiness with which some of Darwin's main concepts appeared to him, although they were logical consequences of his previous ideas. Is this remarkably slow speed of invention one of the conditions of fruitfulness or only a deplorable accident? These are major problems in cognitive psychology that are not yet solved. Nevertheless, we would like to put forward a plausible hypothesis. For a specific subject the speed of transition from one stage to the following one has an *optimal rate*. That is, the stability and even the fruitfulness of a new organization (or structuration) depends on connections which cannot be instantaneous but cannot be indefinitely postponed either since they would then lose their power of internal combination.

IV THE RELATIONS BETWEEN DEVELOPMENT AND LEARNING

13 If we give the name *learning* to every form of cognitive acquisition, it is obvious that development only consists of a sum or a

succession of learning situations. Generally, though, the term is restricted to denote essentially exogenous acquisitions, where either the subject repeats responses, parallel to the repetition of external sequences (as in conditioning), or the subject discovers a repeatable response by using the regular sequences generated by some device, without having to structure or reorganize them himself through a constructive step-by-step activity (instrumental learning). If we accept this definition of learning, the question arises whether development is merely a succession of learned acquisitions (which would imply a systematic dependency of the subject on the objects), or whether learning and development constitute two distinct and separate sources of knowledge. Finally, there is, of course, the possibility that every acquisition through learning in fact represents only a sector or a phase of development itself, arbitrarily provided by the environment (which entails the possibility of a local deviation from the "normal" creodes) but remaining subject to the general constraints of the current developmental stage.

Before we examine the experimental facts, we would like to mention a behaviorist's attempt to reduce our theory to Hull's theory of learning. To effect this reduction, however, Beilyne (1960) was obliged to introduce two new concepts into Hull's theory. The first is stimulus-response generalization, which Hull foresaw but did not use. The second and more fundamental is the concept of "transformational responses," which are not restricted to repetitions but are amenable to reversible transformations in the same way as "operations." In discussing equilibration and regulation, Beilyne extends the concept of external reinforcements, introducing the possibility of "internal reinforcements" such as feelings of surprise, incoherence or coherence. Though these modifications of Hull's theory change its structure fundamentally, it is not certain that they are sufficient. The main question remains, indeed, whether the "transformational responses" are simple copies of observable external transformations of the objects or whether the subject himself transforms the objects by acting on them. The main point of our theory is that knowledge results from *interactions* between the subject and the object, which are

richer than what the objects can provide by themselves. Learning theories like Hull's, on the other hand, reduce knowledge to direct "functional copies" which do not enrich reality. The problem we must solve, in order to explain cognitive development, is that of *invention* and not of mere copying. And neither stimulus-response generalization nor the introduction of transformational responses can explain novelty or invention. By contrast, the concepts of assimilation and accommodation and of operational structures (which are created, not merely discovered, as a result of the subject's activities), are oriented toward this inventive construction which characterizes all living thought.

To close this theoretical introduction to the problem of learning and development we would like to point out how peculiar it is that so many American and Soviet psychologists, citizens of great nations, which intend to change the world, have produced learning theories that reduce knowledge to a passive copy of external reality (Hull, Pavlov, etc.), whereas human thought always transforms and transcends reality. Outstanding sectors of mathematics (e.g., those that involve the continuum hypothesis) have no counterpart in physical reality, and all mathematical techniques result in new combinations which enrich reality. To present an adequate notion of learning one first must explain how the subject manages to construct and invent, not merely how he repeats and copies.

14 A few years ago the International Center of Genetic Epistemology investigated two problems

a Under what conditions can logical structures be learned, and are these conditions identical to those for learning empirical sequences?

b And, even in this last case (probabilistic or even arbitrary sequences), does learning imply a logic analogous, for example, to the logic of the coordinators of action, the existence of which can be observed as early as during the organization of sensorimotor schemes?

On the first point, studies such as those of Greco, Morf, and Smedslund (1959) have shown that in order to learn how to construct and master a logical structure, the subject must start from another, more elementary

logical structure which he will differentiate and complete. In other words, learning is no more than a sector of cognitive development which is facilitated or accelerated by experience. By contrast, learning under external reinforcement (e.g., permitting the subject to observe the results of the deduction he should have made or informing him verbally) produces either very little change in logical thinking or a striking momentary change with no real comprehension.

For example, Smedslund found that it was easy to make children learn the conservation of weight with pieces of clay whose shape was modified and whose constant weight could be read by the child on a pair of scales, because in this case, mere repetition of these observations facilitates generalization. The same processes of reinforcement by observation are not at all sufficient to induce the acquisition of transitivity in the weight equivalences $A = C$ if $A = B$ and $B = C$. In other words, the logical structure of conservation (and Smedslund has checked the correlation between transitivity and operational conservation) is not acquired in the same way as the physical contents of this conservation.

Morf observed the same phenomenon in the learning of the quantification of inclusion $A < B$ if $B = A + A'$. The spontaneous tendency of the child is to compare part A to the complementary part A' whenever his attention is called to the parts of the whole B and B ceases to be preserved as a whole.

By contrast, previous training on the intersection of classes facilitates learning of inclusion. It is true that the Dutch psychologist Kohnstamm (1956) has tried to show that it is possible to teach young subjects the quantitative dominance of the whole over the part ($B > A$) by purely didactic and verbal methods. Hence educational psychologists who believe that educational methods make it possible to teach anything at any age are considered optimistic and the psychologists of the Geneva school who assert that only an adequate spontaneous development makes understanding possible under any circumstance are considered pessimistic. However, the checks on Kohnstamm's experiment now being made in Montreal by Laurendeau and Pinard show that things are not as simple as they appear (ver-

bally trained children make a great many mistakes on the relations between A and A') One can easily understand that teachers of the traditional school will call anyone who believes in their methods an optimist, but, in our opinion, genuine optimism would consist of believing in the child's capacities for invention. Remember also that each time one prematurely teaches a child something he could have discovered for himself, that child is kept from inventing it and consequently from understanding it completely. This obviously does not mean the teacher should not devise experimental situations to facilitate the pupil's invention.

To turn to the second problem we mentioned, Matalon and Apostel have shown that all learning, even empiricist learning, involves logic. This is true in the sense of an organization of the subject's action as opposed to immediate perception of the external data, moreover, Apostel has started to analyze the algebra of the learning process and its necessary basic operations.

15 Following these investigations at the International Center of Genetic Epistemology, Inhelder in Geneva, with her colleagues Bovet and Sinclair (1967), and later Lauen-deau (1966) in Montreal, with her colleagues Fournier-Choninard and Carboneau, have carried out more detailed experiments. The aim of their inquiries was to isolate the various factors which may facilitate an operational acquisition, and to establish the possible relations with the factors involved in the "natural" constructions of the same concepts (e.g., conservation in the course of spontaneous development).

As an example, one of Inhelder, Bovet, and Sinclair's experiments (with Fot) is performed by showing the child transparent jars filled with the same quantities of liquid. Instead of pouring in the usual manner, these jars empty through taps in their bases into glass jars of various shapes, which in turn empty into more jars on other levels. The heights and widths of successive jars vary at each level, but at the bottom of the sequence are jars identical to the ones at the top. This arrangement should lead the child to perform both dimensional and quantitative comparisons and eventually to understand the reason for the equality of the quantities at the starting point and at the end point.

Fig 1 Experimental apparatus for learning the concept of conservation of quantity

It was discovered in this experiment that the results vary very significantly as a function of the initial cognitive levels of the children, which were classified according to the available schemes of assimilation. No child starting at a preoperational level succeeded in learning the logical operations underlying the elementary concepts of the conservation of physical quantities. The great majority (87.5%) did not even show any real progress, while a minority (12.5%) moved up to an intermediate level characterized by frequent oscillations where conservation would be alternatively asserted or denied. This uncertainty is ascribable to the fact that the coordination of the centiations or successive isolated states or then variations were still partial and transient. Clearly, it is one thing to observe that in a closed system of physical transformations nothing is created and nothing destroyed, and quite another to infer from this a principle of conservation. The situation is different with children who initially were already at this intermediate level. In this case only 23% did not achieve conservation, while 77% benefited in various degrees from the exercise and achieved a conservation based on a genuinely operator structure. It is true that for about half of them (38.5%), this result involved only an extension of a structuration already started.

at the time of the pretest, whereas for the other half the gradual construction of the conservation principle was easy to observe during the experiment. Subsequently then reasoning acquired a real stability (there were no regressions in the first and the second posttests). In addition, they were able to generalize conservation, extending the concept to include the transformations of a plasticine ball in a context which outwardly only remotely resembled the previous learning situation. However, in comparing the arguments for conservation given by subjects who had acquired it by the much slower "spontaneous" process, it was observed that they were not entirely identical. The former had constructed a structure that did not make use of all the possibilities of operational mobility, which in its complete form entails general reversibility. In fact, they gave a majority of arguments by identity and compensation, which had been evolved in the experimental situation, and very few arguments by reversibility based on cancellation.

On the other hand, progress in the experimental situation was more general and complete in the cases of children who were initially at an elementary operational level (characterized by the acquisition of conservation of quantity during the experiment) but who had not yet acquired the more complex concept of conservation of weight, which, during spontaneous development, generally appears 2 or 3 years later. In this case progress is genuine when the experimental situation does not restrict the child to passive observation but involves a series of operational exercises (e.g., establishing equality of weight for objects of different sizes, and regardless of position on the scales, and, more essentially, comparing the weights of collections of different objects and establishing their equivalence or nonequivalence). After being subjected to this type of training sequence, 86% of the subjects achieved conservation (in three sessions). Among them, 64% were able to use the transitive properties of order or equality in weight and, using arguments based on total reversibility, showed that they felt these properties were logically evident. These kinds of acquisition are therefore clearly distinct from the pragmatic solution given by children who at a preopera-

tional level were subjected (as in Smeds-lund's experiment) only to empirical evidence.

Essentially what this experiment shows is that learning is subordinate to the subjects' levels of development. If they are close to the operational level, that is, if they are able to understand quantitative relations, the comparisons they make during the experiment are enough to lead them to compensation and conservation. But the farther they are from the possibility of operational quantification, the less they are likely to use the learning sequence to arrive at a concept of conservation.

An experiment carried out by Laurendeau consists of trying to induce progressive de-centration and equilibration, and comparing the results thus obtained to those obtained by Skinner-type operant learning with external reinforcement. One group of subjects is asked to predict the level a liquid will reach when it is poured from one container to another of a different shape. The subjects are then shown the level reached when the liquid is actually poured so that they may see whether their prediction was correct. The subjects are then questioned about conservation, and when they deny it they are asked to add the quantity necessary to make the levels equal. This is repeated with containers whose shape is more and more different, until one is very wide and low and the other very high and thin, and it becomes obvious that equal levels do not produce equal quantities of liquid. In this third part of the experiment 12 gradually higher and thinner containers are used, the median ones (6 and 7) being equal, these are filled by the subject with quantities of liquid he judges to be equal. They are then poured into containers 5 and 8, respectively, the operation is then repeated and 6 and 7 are poured into 4 and 9, etc. With children between 5 and 6 a definite improvement in performance can be observed, and this is corroborated by the posttests given 1 week and 3 months later.

Subjects in a second group are asked to make the same prediction, but then they are asked only questions (some 20 in all) about conservation, correct answers are suitably rewarded. In fact, the child is very quickly able to give only correct answers and can still do

this 2 or 3 days later, but posttests show that his learning is much more limited and less stable

To summarize, learning appears to depend on the mechanisms of development and to become stable only insofar as it utilizes certain aspects of these mechanisms, the instruments of quantification themselves, which would have evolved in the course of spontaneous development

V THE OPERATIVE AND FIGURATIVE ASPECTS OF COGNITIVE FUNCTIONS

16 The stages described in Section III are only those concerning the development of intelligence, and the aspects of learning considered in Section IV are only relevant to these stages

If we wish to obtain a complete picture of mental development, we must not only consider the operative aspect of the cognitive functions, but also their figurative aspect. We will call *operative* the activities of the subject that attempt to transform reality (*a*) the set of all actions (except those which, like imitation or drawing, are purely accommodatory in intent) and (*b*) the operations themselves. "Operative" is thus a broader term than "operational," which is only related to the operators. In contrast, we shall call *figurative* the activities which attempt only to represent reality as it appears, without seeking to transform it (*a*) perception, (*b*) imitation, in a broad sense (including graphic imitation or drawing), and (*c*) pictorial representations in mental imagery.

Before discussing these figurative aspects and their relations with the operative aspects of knowledge, we must briefly analyze their relations with the semiotic function (generally called symbolic function). In considering semiotic functions, Piaget introduced a distinction between "indexes" (perceptions), "icons" (images), and symbols, in which he included language. We prefer de Saussure's terminology, which is more widely used in linguistics, and which is characterized psychologically in the following way

→ SAUSSURE.

a Indexes are signifiers that are not differentiated from their significant since they are part of them or a causal result for example

for an infant, hearing a voice is an index of someone's presence

b Symbols are signifiers that are differentiated from their significant, but they retain a measure of similarity with them, for example in a symbolic game representing bread by a white stone and vegetables by grass

c Signs are signifiers that are also differentiated from their signifiers but are conventional and thus more or less "arbitrary" the sign is always social, whereas the symbol can have a purely individual origin as in symbolic games or in dreams

We shall thus call the semiotic function (or symbolic function, but semiotic has a broader meaning) the ability, acquired by the child in the course of his second year, to represent an object which is absent or an event which is not perceived, by means of symbols or signs, that is, of signifiers differentiated from their significant. (Thus the semiotic function includes in addition to language, symbolic games, mental and graphic images (drawings), and deferred imitation (beginning in the absence of its model), which appears nearly at the same time (except for drawing, which appears slightly later), whereas indexes (including the "signals" involved in conditioning already play a role during the first weeks. The transition from indexes to symbols and signs—in other words, the beginning of the differentiation which characterizes the semiotic function—is definitely related to the progress of imitation, which at the sensorimotor level, is a sort of representation through actual actions. As imitation becomes differentiated and interiorized in images, it also becomes the source of symbols and the instrument of communicative exchange which makes possible the acquisition of language.)

Thus defined, the semiotic function partially includes the figurative activities of knowledge, which in their turn partially include the semiotic function. There thus exists an intersection between their respective domains but not equivalence or inclusion. In effect, perception is a figurative activity, but it does not belong to the semiotic function since it uses only indexes and no representative signifiers. Language belongs to the semiotic function, but it is only partly figurative (mainly when the child is young, or less so with increased

age, especially with the onset of formal operations) In contrast, imitation, mental imagery, and drawing are both figurative and semiotic

17 The discussion of perception here is very brief, Seagum's excellent translation of the author's *Perceptual Mechanisms* (1961) will be published in the near future However, it is relevant to note here that, during our study of the development of perception in the child, we have been led to distinguish between "field effects" (field being understood here as field of visual motor centiation, not as field in the sense of Gestalt theory) and the perceptual activities of exploration such as visual transports, relating, and visually placing in reference (as far as position or direction are concerned)

Field effects quantitatively decrease with age (this is the case for the primary optico-geometrical illustrations such as Muller-Lyer's), but they retain their qualitative characteristics Consequently, their evolution with age does not yield a succession of stages For instance, based on the concept of visual centiations (studied with Vinh-Bang in ocular movements) we have been able to construct a probabilistic model of "encounters" and "couplings" (through successive centiations) which gives a general law for the plane primary illusions and can be used to compute for each one its theoretical positive and negative maximum point These points have been checked experimentally and remain the same at every age, though the quantitative amount of the illusion decreases

In contrast, perceptual activities are modified with age and roughly approximate stages can be distinguished For example, if one exposes the same subject to 20 or 30 presentations of the Muller-Lyer or lozenge illusion (underestimation of the main diagonal), one observes an effect of learning which increases with age after 7 years Noeltig and Gonheim were able to show that it did not appear before 7 This perceptual learning (which is dependent on autoregulations or spontaneous equilibrations) is not reinforced, since the subject does not know the error in his estimate, it is the result of perceptual activities which become more efficient with age

Moreover, while studying the way in which children perceptually estimate the horizontality of a line (e.g., in a tilted triangle), we

found (with Dadsetan) a real improvement toward 9 to 10 years, which is in direct correlation with the corresponding spatial operations Here, as in all the cases in which we could study the relations between perception and intelligence, it is intelligence which directs the movements, naturally not by experimenting with the perceptual mechanisms but by indicating what must be looked at and which indexes are useful in making a good perceptual estimate

18. We have studied mental images extensively with Inhelder (1966) and many other colleagues, especially considering their relations to intelligence (e.g., by asking subjects to imagine the result of pouring a liquid into a different container in a conservation experiment, before they have actually seen the result) Our first conclusion is that the image does not come from perception (it only appears at approximately 1½ years together with the semiotic function) and that it obeys completely different laws It is probably the result of an interiorization of imitation This hypothesis seems corroborated in the domain of symbolic games in their initial stages (fiction or imagination games, which show all the transitions between imitative symbols by gestures and actions and interiorized imitation or images)

Further, if one distinguishes "reproductive" images (to imagine an object or an event which is known but is not actually perceived at the time) and "anticipatory" images (to imagine the result of a new combination), our results have shown the following

a Before 7 years, one can find only reproductive images, and all of them are quite static For example, the subjects experience systematic difficulty in imagining the intermediate positions between the initial vertical and final horizontal position of a falling stick

b After 7 to 8 years, anticipatory images appear, but they are not only applied to new combinations They also seem to be necessary for the representation of any transformation even if it is known, as if such representations always entailed a new anticipation

But this research has shown above all the strict interdependency between the evolution of mental images and the evolution of operations Anticipatory images are possible only when the corresponding operations exist In

our experiments concerning conservation of liquids the younger subjects go through a stage of "pseudo-conservation" where they imagine that in a narrow container the level of the liquid would be the same as in a wide one (and it is only when they see that it is not the same level that they deny conservation). About 23% of the subjects know the level will rise, but this knowledge is contained in a reproductive image (founded on experience) and they conclude that there will be no conservation (when asked to pour the "same quantity" in the two containers, they pour liquid up to the same levels).

In short, while mental images can sometimes facilitate operations, they do not constitute their origin. On the contrary, mental imagery is generally controlled by the operations gradually as they appear (and one can follow their construction stage by stage).

19 The study of mental imagery led us to investigate the development of memory. Memory has two very different aspects. On the one hand, it is cognitive (entailing knowledge of the past), and in this respect it uses the schemes of intelligence, as we shall show shortly in an example. On the other hand, imagery is not abstract knowledge and bears a particular and concrete relation to objects or events. In this respect such symbols as mental images and, more specifically, "memory images" are necessary to its operation. Images themselves can be schematized, but in an entirely different sense, for images in themselves, however schematic, are not schemes. We shall therefore use the term *schemata* to designate them. A schema is a simplified image (for example, the map of a town), whereas a scheme represents what can be repeated and generalized in an action (e.g., the scheme is what is common in the actions of "pushing" an object with a stick or any other instrument).

The main result of our research has been, in this context, to show not the generality but the possibility that progress in memory is influenced by improvements in the operational schemes of intelligence. For example, we showed (with Sinclair and others) 3- to 8-year-old children an array of 10 wooden bars varying in length between 9 and 16 cm arranged according to their length, and we merely asked the subjects to look at the array. A week, and then a month later they were asked to draw the array from memory.

The first interesting result is that, after 1 week, the younger children do not remember the sequence of well-ordered elements, but reconstruct it by assimilating it to the schemes corresponding to their operational level: (a) a few equal elements, (b) short ones and long ones, (c) groups of short, medium, and long ones, (d) a correct sequence, but too short, (e) a complete sequence. The second remarkable result is that after 6 months (without any new presentation, memory was improved in 75% of the cases. Those who were at level *a* moved up to *b*. Many at level *b* moved up to *c* or even *d*. The *c*'s moved up to *d* or *e*, etc. The results, naturally, are not as spectacular in other experiments, and there is less progress as the model is less schematizable (in the sense of being made schematic, and not being assimilated to a scheme). The existence of such facts shows that the structure of memory appears to be partly dependent on the structure of the operations.

VI THE CLASSICAL FACTORS OF DEVELOPMENT

20 We have seen that there exist laws of development and that development follows a sequential order such that each of its stages is necessary to the construction of the next. But this fundamental fact remains to be explained. The three classical factors of development are maturation, experience of the physical environment, and the action of the social environment. The two last cannot account for the sequential character of development, and the first one is not sufficient by itself because the development of intelligence does not include a hereditary programming factor like the ones underlying instincts. We shall therefore have to add a fourth factor (which is in fact necessary to the coordination of the three others—equilibration, or self-regulation (*auto régulation*)).

① It is clear that maturation must have a part in the development of intelligence, although we know very little about the relations between the intellectual operations and the brain. In particular, the sequential character of the stages is an important clue to their partly biological nature and thus argues in favor of the constant role of the genotype and epigenesis. But this does not mean we can assume there exists a hereditary program underlying

the development of human intelligence there are no "innate ideas" (in spite of what Lorenz maintained about the a priori nature of human thought) Even logic is not innate and only gives rise to a progressive epigenetic construction Thus the effects of maturation consist essentially of opening new possibilities for development, that is, giving access to structures which could not be evolved before these possibilities were offered But between possibility and actualization, there must intervene a set of other factors such as exercise, experience, and social interaction

A good example of the gap that exists between the hereditary possibilities and their actualization in an intellectual structure can be provided by an inspection of the Boolean and logical structures discovered by McCulloch and Pitts (1947) in the neural connections In this context the neurons appear as operators which process information according to rules analogous to those of the logic of propositions But the logic of propositions only appears on the level of thought at around 12 to 15 years of age Thus there is no direct relation between the "logic of the neurons" and that of thought In this particular case, as in many others, the process must be conceived of not as progressive maturation, but as a sequence of constructions, each of which partly repeats its immediate predecessor but at a very different level and on a scope that goes far beyond it What makes possible the logic of neurons is initially exclusively a nervous activity But this activity makes possible in its turn a sensorimotor organization at the level of behavior However, this organization, while retaining certain structures of the nervous activity, and consequently being partially isomorphic to it, results at first in a set of connections between behaviors which is much simpler than that of the nervous activity itself because these behaviors have to correlate actions and objects and are no longer limited to exclusively internal transmissions Further, the sensorimotor organization makes possible the constitution of thought and its symbolic instruments, which imply the construction of a new logic, partially isomorphic to the previous ones, but which is confronted with new problems, and the cycle repeats The propositional logic which is constructed between 12 and 15 years is thus by no means the immediate consequence of the logic of neurons, but

it is the result of a sequence of successive constructions that are not preformed in the hereditary nervous structure but are made possible by this initial structure So we are now very far from a model of continuous maturation which would explain everything by preformed mechanisms For this purely endogenous model, there must be substituted a series of actual constructions, the sequential order of which does not imply a simple predetermination but involves much more than this

21 A second factor traditionally invoked to explain cognitive development is *experience* acquired through contact with the external physical environment This factor is essentially heterogeneous, and there are at least three categories and meanings of experience, among which we shall distinguish two opposite poles

a The first is simple *exercise*, which naturally involves the presence of objects on which action is exerted but does not necessarily imply that any knowledge will be extracted from these objects In fact, it has been observed that exercise has a positive effect in the consolidation of a reflex or of a group of complex reflexes such as sucking, which noticeably improves with repetition during the first days of life This is also true of the exercise of intellectual operations which can be applied to objects, although these operations are not derived from the objects In contrast, the exercise of an exploratory perceptual activity or of an experiment can provide new exogenous information while consolidating the subject's activity We can thus distinguish two opposite poles of activity in exercise itself: a pole of accommodation to the object, which is then the only source of the acquisitions based on the object's properties, and a pole of functional assimilation, that is, of consolidation by active repetition In this second perspective, exercise is predominantly a factor of equilibrium or autoregulation, that is, it has to do with structurations dependent on the subject's activity more than with an increase in the knowledge of the external environment

As regards experience proper in the sense of acquisition of new knowledge through manipulations of objects (and no longer through simple exercise), we must again distinguish two opposite poles, which will correspond to categories (b) and (c)

b There is what we call *physical experience*, which consists of extracting information from the objects themselves through a simple process of abstraction. This abstraction reduces to dissociating one newly discovered property from the others and disregarding the latter. Thus it is physical experience that allows the child to discover weight while disregarding an object's color, etc., or to discover that with objects of the same nature, their weight is greater as their volume increases, etc.

c In addition to physical experience (*b*) and to simple exercise (*a*), there is a third fundamental category, which strangely practically never has been mentioned in this context. This is what we call *logicomathematical experience*. It plays an important part at all levels of cognitive development where logical deduction or computation are still impossible, and it also appears whenever the subject is confronted with problems in which he has to discover new deductive instruments. This type of experience also involves acting upon objects, for there can be no experience without action at its source, whether real or imagined, because its absence would mean there would be no contact with the external world. However, the knowledge derived from it is not based on the physical properties of these objects but on properties of the actions that are exerted on them, which is not at all the same thing. This knowledge seems to be derived from the objects because it consists of discovering by manipulating objects, properties introduced by action which did not belong to the objects before these actions. For example, if a child, when he is counting pebbles, happens to put them in a row and to make the astonishing discovery that when he counts them from the right to the left he finds the same number as when he counts from the left to the right, and again the same when he puts them in a circle, etc., he has thus discovered experimentally that the sum is independent of order. But this is a logicomathematical experiment and not a physical one, because neither the order nor even the sum was in the pebbles before he arranged them in a certain manner (i.e., ordered them) and joined them together in a whole. What he has discovered is a relation, new to him, between the action of putting in order and the action of joining together (hence, between

the two future operations), and not, or *not only*, a property belonging to pebbles.

Thus we see that the factor of acquired experience is, in fact, complex and always involves two poles: acquisitions derived from the objects and constructive activities of the subject. Even physical experience (*b*) is never pure, since it always implies a logicomathematical setting, however elementary (as in the geometrical Gestalts of perception). This amounts to saying that any particular action such as "weighing" that results in physical knowledge is never independent of more general coordinations of action (such as ordering, joining together, etc.) which are a source of logicomathematical knowledge.

22 The third classical factor of development is the influence of the social environment. Its importance is immediately verified if we consider the fact that the stages we mentioned in Section III are accelerated or retarded in their average chronological ages according to the child's cultural and educational environment. But the very fact that the stages follow the same sequential order in *any* environment is enough to show that the social environment cannot account for everything. This constant order of succession cannot be ascribed to the environment.

In fact, both social or educational influences and physical experience are on the same footing in this respect; they can have some effect on the subject only if he is capable of assimilating them, and he can do this only if he already possesses the adequate instruments or structures (or their primitive forms). In fact, what is taught, for instance, is effectively assimilated only when it gives rise to an active reconstruction or even reinvention by the child.

An excellent example of this complex situation is provided by the difficult problem of the relations between language and thought. Many authors have maintained that language is not only the essential factor in the constitution of representation or thought, which raises a first question, but also that language is the origin of the logical operations themselves (e.g., classification, order, propositional operations), which raises a second question.

With respect to the first question, it is doubtless true that language plays a major part in the interiorization of action into representation and thought. But this linguistic

factor is not the only one at work. We must refer to the symbolic or semiotic function as a whole—and language is only a part of this. The other instruments of representation are deferred imitation, mental imagery (which is an interiorized imitation and not a mere extension of perception), symbolic games (or games of imagination), drawing (or graphical imitation), etc., and it is certainly imitation in the general sense which constitutes the transition between the sensorimotor and semiotic functions. Thus it is in the general context of the semiotic function that language must be considered, however important its part may be. The study of deaf-mutes, for example, shows how far the other symbolic instruments can reach when the development of articulate language is disturbed.

Turning to the question of the relations between language and logical operations, we have always maintained that the origin of logical operations is both deeper than and genetically prior to language, that is, it lies in the laws of the general coordinations of action, which control all activities including language itself.

An elementary logic already exists in the coordination of the sensorimotor schemes (cf. Section I: the group of translations, the conservation of the objects, etc.). It exists in a form of intelligence which is yet neither verbal nor symbolic. But there still remains to establish more precisely the relations between language and the logical operations on the level of interiorized thought.

This has recently been done by Sinclair in a set of experiments at the psychological and linguistic level, which are most instructive. She studied two groups of 5- to 7-year-old children, one clearly at a preoperational stage and unable to attain the concept of conservation, whereas the other possessed all the instruments that lead to conservation. She was then able to show that their language is on the average noticeably different when one examines them on subjects other than conservation; for instance, when one asks them to compare two or more objects such as a long, thin pencil and a short, thick one. The preoperational group uses mainly the nonrelational terms of a scale: "this one is long, this one is short, this one is thick, and this one is thin." The operational group, in contrast, uses mainly "vectors": "this one is smaller and

thicker," etc. There is thus a clear relation between linguistic and operational level (and this is also true in other situations). But in which direction? To establish this, Sinclair then taught a group of younger subjects to use the verbal forms used by the older ones. Once this was done she again investigated their operational level and discovered that only approximately 10% had improved, this very small proportion could even represent intermediate cases, or cases who were already very near the operational threshold. We can thus observe that language does not seem to be the motor of operational evolution but rather an instrument in the service of intelligence itself. (See Sinclair and Zwart, 1967).

To conclude ¶ 20, 21, and 22, it appears that the traditional factors (maturation, experience, social environment) are not sufficient to explain development. We must therefore appeal to a fourth factor, equilibration, and we must do this for two reasons. The first is that these three heterogeneous factors cannot explain a sequential development if they are not in some relation of mutual equilibrium, and that there must therefore exist a fourth organizing factor to coordinate them in a consistent, noncontradictory totality. The second reason is that any biological development is, as we now know, self-regulatory, and that self-regulating processes are even more common at the level of behavior and the constitution of the cognitive functions. We must thus consider this factor separately. ✓

VII. EQUILIBRATION AND COGNITIVE STRUCTURES

23. The main aim of a theory of development is to explain the constitution of the operational structures of the integrated whole or totality (*structure opératoire d'ensemble*) and we believe only the hypothesis of progressive equilibration can account for it. To understand this we must first briefly consider the operational structures themselves.

The concept of structure became classical in psychology when it was introduced by Gestalt theory to combat association and its atomistic habits of thought. But the Gestaltists conceived of only one type of structure as applicable to the whole of psychology, from perception to intelligence. They did not distinguish two characters, which in reality

are quite different. The first is common to all structures, they all possess holistic laws derived from the fact that they form a system, and these laws are distinct from the properties of the elements in the totality. The second character is nonadditive composition, that is, the whole is quantitatively different from the sum of the parts (as in Oppel's perceptual illusion). But in the field of intelligence, there exist structures which verify the first characteristic and not the second, the set of integers, for instance, has holistic properties as such ("group," "ring," etc.), but composition in it is strictly additive— $2 + 2 = 4$, no more, no less.

We have therefore attempted to define and analyze the structures specific to intelligence, and they are structures involving operations, that is, involving interiorized and reversible actions such as addition, set-theoretic union, logical multiplication, or, in other words, composition of a multiplicity of classes or relations "considered simultaneously." These structures have a very natural and spontaneous development in the child's thought to seriate, for instance (i.e., to order objects according to their increasing size), to classify, to put into one-to-one or one-to-many correspondence, to establish the multiplicative matrix, are all structures that appear between ages 7 and 11, at the level of what we call "concrete operations" which deal directly with objects. After 11 to 12 other structures appear, such as the four-group and combinatorial processes, which we shall describe later.

To investigate the properties of these concrete operational structures, and to establish their laws, we need to use the language of the logic of classes and relations, but this does not mean we are leaving the field of psychology. When a psychologist computes the variance of a sample or uses the formulas of factor analysis, it does not mean his field has become statistics and not psychology. To analyze structures we must do the same, but, since we are not dealing with quantities, we must simply resort to more general mathematical instruments such as abstract algebra or logic. But they are only instruments which will allow us to reach genuinely psychological entities such as operations, considered as interiorized actions or general coordinations of actions.

A totality structure such as a classification

has the following properties, which characterize, simply, the operations that are actually present in the subject's action.

a He can combine one class A with another A' , to obtain class B , denoted $A + A' = B$ (he can then go on to perform $B + B' = C$, etc.)

b He can dissociate A or A' from B , denoted $B - A' = A$, which constitutes the inverse operation. Notice this reversibility is necessary to the understanding of the relation $A < B$, and we know that until 7 or 8, the child does not grasp easily the idea that if he is given 10 primroses A , and 10 other flowers A' , then there are more flowers B than primroses A , because to be able to compare the whole B to the part A , one must be able to combine the two operations $A + A' = B$ and $A = B - A'$, otherwise the whole B is not preserved, and A is then only compared to A' .

c He will understand that $A - A = 0$, and $A + 0 = A$.

d Finally, he will be able to associate $(A + A') + B' = A + (A' + B') = C$, while $(A + A) - A = 0$ is not equal to $A + (A - A) = A$.

We have called *groupements* these elementary groupings⁷ (*structures de groupoides*),

⁷ A grouping can be considered as a lattice that has been made reversible. In a lattice, if $A + A' = B$, where B is an upper bound of A and A' , A can be recovered by operating on B : $B - A' = A$. But the more general case is where C is an upper bound of A and C' , for example, and $A \pm D = C'$. In other words, the operation $A + A'$ can only be "reversed" between contiguous elements such as A and A' , in the sense that in the 3-tuple A, A', B any two elements uniquely determine the third (Fig. F7a).

This is not the case for A, C', D , where $A + C' = D - D' - B' - A'$. Here we consider a grouping as a group where composition is restricted to contiguous elements only ($A + C'$, for example, is not defined without special conditions) and by the special identities $A + A = A$, $A + B = B$. A grouping is therefore only defined as a sequence of nested elements, such as a classification (Fig. F7b). It consists of (a) a direct operation (b) an inverse operation (c) an identity operation O and (d) special identities

$$\begin{aligned} A + A' &= B \\ B - A' &= A \\ A + O &= A, & A - A &= O \\ A + A &= A, & -A - A &= -A, \\ A + B &= B \end{aligned}$$

Fig F7a

Fig F7b

✓ which are more primitive than mathematical groups, but which are also much more limited structures and less elegant ones, in that composition is defined only between neighboring elements without general combinatorial properties and shows restricted associativity.⁸ We have often been criticized for having thus only constructed structures that have no psychological reality. But such structures actually exist, primarily because they describe simply what happens in a classification, a seriation, etc., all

⁸ Associativity is limited by the fact that the grouping only combines contiguous elements. $A + C'$ can only be constructed by operating step-by-step on the nearest contiguous classes $A, A', B',$ up to D , the first class containing both A and C' , then $A + C' = D - B' - A'$. Similarly, $A - C'$ only gives rise to the tautology $A - C' = (D - C' - B' - A') - C'$ where $(D - C' - B' - A') = A$. The consequence of these restrictions is that associativity is not verified before the elements in brackets have first been "reduced" ($A + A') + B' = B + B' = C$, but $A + (A' + B')$ has no meaning since $(A' + B')$ and is not defined as such. (For further details of the reduction rules, cf. Piaget, 1959.) In contrast, on the group of the integers under addition any number can be immediately added to or subtracted from any other because an integer can be completely freed from its successors that "contain" it (Translator's note).

of which are quite contemporaneous behaviors. Moreover, they can be recognized on the psychological level by the more general characters that reveal the existence of a totality structure, such as transitivity (for instance, in a seriation $A < C$ if $A < B$ and $B < C$) and the constitution of conservation concepts (conservation of a whole B when the arrangement of its parts A and A' is modified, conservation of length, quantity, etc.). ✓

24 The problem then becomes that of understanding how the fundamental structures of intelligence can appear and evolve with all those that later derive from them. Since they are not innate, they cannot be explained by maturation alone. Logical structures are not a simple product of physical experience, in seriation, classification, one-to-one correspondence, the subject's activities add new relations such as order and totality to the objects. Logicomathematical experience derives its information from the subject's own actions (as we saw in ¶21), which implies an autoregulation of these actions. It could be alleged that these structures are the result of social or educational transmission. But as we saw (¶22), the child must still understand what is transmitted, and to do this the structures are necessary. Moreover, the social explanation only displaces the problem: how did the members of the social group acquire the structures in the first place? ✓

But on all levels of development actions are coordinated in ways that already involve some properties of order, inclusion, and correspondence, and also foreshadow such structures (e.g., seriation for order, classification for inclusion, multiplicative structures for correspondence). What is more important, though, is that coordination of actions involves correction and self-regulation, in fact, we know regulatory mechanisms characterize all levels of organic life (this is true for the genetic pool as well as for behavior). But regulation is a process of retroaction (negative feedback), which implies a beginning of reversibility, and the relationship between regulation (which is correction of error with semireversibility in the retroaction) and operation, whose full reversibility allows for piecemeal correction of errors (i.e., for "perfect" regulation in the cybernetic sense) becomes apparent.

Thus it seems highly probable that the

construction of structures is mainly the work of equilibration, defined not by balance between opposite forces but by self-regulation, that is, equilibration is a set of active reactions of the subject to external disturbances, which can be effective, or anticipated, to varying degrees. Equilibrium thus becomes identical with reversibility, but when one objects (as Bruner does, for example) that equilibrium therefore becomes superfluous, because reversibility is sufficient in itself, one forgets that it is not only the final state of equilibrium that must be considered, but that *equilibration* is essential as the self-regulating process leading to this final state and thus to the reversibility that characterizes the structures that must be explained.

25 Equilibration has explanatory value because it is founded on a process with increasing sequential probabilities. We can understand this better through an example. How can we explain the fact that when a spherical lump of clay is changed into the shape of a sausage in front of him, a child will begin by denying that the quantity of clay is preserved under this transformation, and end by asserting the logical necessity of this conservation? To do this we must define four stages, each of which *becomes more probable*, not a priori, but as a function of the present situation or of the one immediately preceding it.

a Initially the child considers only one dimension, for instance, length (say 8 times out of 10). He then says the sausage contains more matter because it is longer. Sometimes (say 2 times out of 10) he says it is thinner, but forgetting its greater length, he concludes the quantity of matter has decreased. Why does he reason thus? Simply because the probability of considering one dimension only is greater. If the probability for length is 8 and that for width is 2, that for length *and* width is 16, because they are independent occurrences as long as compensation is not understood.

b If the sausage is made longer and longer, or if the child becomes weary of repeating the same argument, the probability of his noticing the other dimension *becomes* greater (though it was not initially) and he will fluctuate between the two.

c If there is oscillation, the probability

of the subject's noticing some correlation between the two variations (when the sausage becomes longer it becomes thinner) *becomes* greater (third stage). But as soon as this feeling of the solidarity existing between variables appears, his reasoning has acquired a new property: it does not rest solely on *configurations* any more but begins to be concerned with *transformations*: the sausage is not simply "long", it can "lengthen," etc.

d As soon as the subject's thought takes transformations into account, the next stage *becomes* more probable in which he understands (alternately or simultaneously) that a transformation can be reversed, or that the two simultaneous transformations of length and width compensate, because of the solidarity he has glimpsed [see stage (c)].

We can thus see that progressive equilibration has effective explanatory value. Stage (a) (which all those who checked our research have found) is not an equilibrium point because the child has noticed only one dimension; in this case the algebraic sum of the virtual components of work (to quote d'Alembert's principle on physical systems) is not zero since one of them, which consists of noticing the other dimension, has not been completed yet and will be sooner or later. The transition from one stage to another is therefore an equilibration in the most classical sense of the word. But since these displacements of the system are activities of the subject, and since each of these activities consists of correcting the one immediately preceding it, equilibration becomes a sequence of self-regulations whose retroactive processes finally result in operational reversibility. The latter then goes beyond simple probability to attain logical necessity.

What we have just said about an instance of operational conservation could be repeated about the construction of every operational structure. Seriation $A < B < C$, for example, when it becomes operational, is the result of coordinating the relations $<$ and $>$ (each new element in E in the ordered sequence having the property of being both $> D, C, B, A$, and $< F, G, H$), and this coordination is again the result of an equilibration process of increasing sequential probabilities of the kind we have described. Similarly for inclusion of classes, $A < B$ if $B = A + A'$ and

$A' > O$ is obtained by an equilibration of the same type

It is not therefore an exaggeration to say that equilibration is the fundamental factor of development, and that it is even necessary for the coordination of the three other factors.

VIII THE LOGICOMATHEMATICAL ASPECTS OF STRUCTURES

26 The "concrete" operational structures we have just mentioned all presuppose the construction of certain quantities: extension of classes for classification (which explains the difficulty of quantifying the inclusion of classes), size of the differences for seriation, quantitative conservations, etc. (But even before these quantitative structures are constructed, some partial and qualitative structures may be observed at the preoperational levels which are of great interest, because they constitute the first half, so to speak, of the logic of reversible operations. These are the directional functions (one-way functions that do not have inverses, which would imply reversibility) and the qualitative identities (see ¶ 10).)

The functions, we remember are "mappings" in the mathematical sense, which have no inverses because, as we saw, they are psychologically related to the schemes of action, which are goal-directed. Suppose, for instance, we have a piece of string b , part a of which is at right angles to the rest (a') and can slide on a nail when a weight is connected with a' and a is held back by a spring. All children between 4 and 7 understand that if one pulls b , a grows shorter as a' grows longer. But they do not yet have conservation of the length of the whole b ($b = a + a'$), and what they perform is not a quantified operation but simply a qualitative or ordinal equation (longer = farther).

Similarly for identity, all children (or nearly all) agree, as we saw, that when a ball of clay is changed into a sausage, it is the "same" lump of clay even if quantity is not preserved. These identities are acquired early and the scheme of permanent objects we mentioned in ¶ 2 is one of them. In a recent book, Bruner considers them the origin of quantitative conservations. This is true in a sense (they are a necessary condition but not a sufficient one), but a cen-

tial difference remains: qualities (on which qualitative identity is founded) can be established perceptually, whereas quantity involves a lengthy structural elaboration whose complexity we have just seen (¶ 23 to 26).

In fact, functions and qualitative identity constitute only that half of a logic which is both preoperational and qualitative and leads to the logic of reversible and quantitative operations but is not powerful enough to account for it.)

27. This quantification of concrete operations, as opposed to the qualitative nature of preoperational functions and identities, is revealed in particular by the construction, around 7 or 8, of the operations related to number and measure, which are partly isomorphic to one another but have very different content. The construction of cardinal numbers cannot be explained, as was believed by Russell and Whitehead, simply by one-to-one correspondence between equivalent classes, because the correspondence they used, by abstraction of qualities (in contrast with qualified correspondence between individual objects with the same properties) implicitly introduced unity and therefore number, which made their reasoning circular. In fact, when we deal with finite sets cardinal numbers cannot be dissociated from ordinal numbers and are subject to the three following conditions:

a Abstraction from qualities, which makes all singular objects equivalent and therefore $1 = 1 = 1$

b The intervention of order $1 \rightarrow 1 \rightarrow 1$, which is necessary to distinguish the objects from one another—otherwise $1 + 1 = 1$ would be true

c An inclusion of (1) in $(1 + 1)$, then of $(1 + 1)$ in $(1 + 1 + 1)$, etc

The integers thus result from synthesis of order (seriation) and inclusion or nested sets (classification), which is made necessary by the abstraction from qualities. Hence the integers are built up from purely logical elements (seriation and classification), but they are rearranged in a new synthesis which allows for their quantification by an iterative process $1 + 1 = 2$, etc.

Similarly, measurement in a continuum (e.g., a line, a surface) implies (a) its partition into segments one of which is then

chosen as unity and made equivalent to others by congruence $a = a = a$, (b) its translation in a certain order, $a \rightarrow a \rightarrow a$, etc., to make it congruent to others, and (c) the units settling into its additive compositions, thus a into $(a + a)$ and $(a + a)$ into $(a + a + a)$. This synthesis of partition with nested segments and order in the translations of unity is thus isomorphic to the synthesis of order and inclusion which characterizes number, and this makes it possible to apply number to measurement.

It is thus clear that without having recourse to anything other than the synthesis of elementary "groupings" of inclusion or order relations, the subject attains a numerical or metrical quantification whose power by far surpasses the elementary quantification (relations from part to whole) of the extension of classes or of seriation based on differences evaluated simply by "more" or "less."

28. After the concrete operational structures mentioned in §23, two other new structures are constructed between ages 11

⁹ The INRC group is a set of operations that act on the operations or elements of some other algebraic structure which has an involutive operation (an operation which is its own inverse $N^2 = I$). An example of an involutive operation is the duality (de Morgan) law of Boolean algebra $\overline{p \cup q} = \overline{p} \cap \overline{q}$, which we can write $N(p \cup q) = \overline{p} \cap \overline{q}$ (N for negative). If we define C (correlative) to be the rule that acts on the connectives, changing \cap into \cup and conversely, and R (reciprocal) to be the rule that acts on the sign of the variables, changing p into \overline{p} and conversely, then by using C and R in succession [on, say $(p \cup q)$], we get the same result as by using N . The following "state diagram" shows the relations between N , R , and C acting on $(p \cup q)$.

Identity I can now be defined as the rule that changes any formula into itself, and the following properties can easily be verified by "chasing around the diagram":

a $RC = N$, $RN = C$, $CN = R$, and all couples are commutative— $RC = CR$, etc.

b $C^2 = N^2 = R^2 = I$ (all transformations are involutive, i.e., each element has an inverse)

c $RNC = I$

and 15 which make possible the manipulation of such propositional operations as implications ($p \supset q$), incompatibilities ($p \mid q$), and disjunctions ($p \vee q$), etc. These two new structures are the four-group and combinatorial operations. Combinatorial activity at this stage consists of classifying all possible classifications (just as permutations are a seriation of seriations) aa, ab, ac, bc, bb, cc , etc., and this does not therefore constitute an entirely new operation but an operation on other operations. Similarly, the four-group INCR⁹ results from connecting in a whole the inversions N and reciprocities R (thus the inverse of the reciprocal $NR = C$ appears, as well as the identity operation $I = NCR$). But inversion already exists in the groupements of classes, under the form $A - A = O$, and reciprocity exists under the form $A = B$ therefore $B = A$ in the groupements of relations. The INRC group is thus again an operational structure bearing on prior operations. As for the propositional operations, $p \supset q$, etc., which involve both combina-

From this we can show the set $[I, N, R, C]$ together with the operation of composition (in the usual sense of applying one transformation on the result of another) forms a noncyclic group of four elements (known as the Klein four-group).

The INRC group can also be defined on physical systems that have the proper structure (i.e., an involutive transformation that can be "decomposed" into two other involutive transformations). In one of his experiments on double reference-systems Piaget uses a snail, which can move from left to right and conversely on a small board, which can itself be moved both ways on a table. We can define C to be the rule that reverses the movement of the snail $C(L, L) = (R, L)$, for example [where (R, L) means the snail (first coordinate) is moving right, and the board moving left]. Then we can define R to be the rule that reverses the second coordinate, for example, $R(L, L) = (L, R)$ (this reverses the movement of the board). The "state diagram" has the same structure as before, and N (N reverses both movements) is the product of R and C .

(Translator's note)

torial activity and the INRC group, they are new in their form, but in their content they deal with connections between classes, relations, or numbers, etc., and are therefore again operations on operations.

In general, the operations belonging to the third period of development (see ¶ 10, period *c* for ages 11 to 12) have their roots in concrete operations (subperiod *b II*, between 7 and 11) and enrich them, just as the source of concrete operations is in the sensorimotor schemes (period *a*, until about 2) which they also considerably modify and enrich. The sequential character of the stages (which we sufficiently stressed in ¶ 10) thus corresponds from the point of view of the construction of structures to a mechanism which we must now analyze, because it is too important for us to merely call it a sequential or progressive equilibration process. We must still understand how the constructions that bring about novelty occur, and this is a well-known problem in the development of mathematical structures.

29. We saw (¶ 21c) that before the level at which logicomathematical operations are constructed and thus become a deductive system we can speak of logicomathematical experiments, which extract information from the properties of actions applied to objects, and not from the objects themselves, which is quite another matter. We thus have, in contrast with abstraction proper, a new type of abstraction which we shall call *reflective abstraction* and which is the key to our problem. To abstract a property from an action or an operation, it is not enough to dissociate it from those that will be disregarded (e.g., a dissociation between the "form" to be retained and the "content" to be disregarded), the property or form thus retained must in addition be transferred somewhere, that is, on a different plane of action or operation. In the case of abstraction proper this question does not appear since we are dealing with a property of an object, which is assimilated by the subject. In the case of *reflective abstraction*, however, when the subject extracts a property or a form from actions or operations on a plane P_1 , he must then transfer it to a higher plane P_2 , and this is thus a reflection in a quasi-physical sense (as in the reflection of a light beam). But for this form or property to be assimilated on

this new plane P_2 , it must be reconstructed on this new plane and therefore subjected to a new thought process which will this time mean "reflection" in a cognitive sense. Thus it is in both senses of the word that we must understand "reflective abstraction."

But if a new cognitive processing is necessary on plane P_2 to assimilate the properties or forms abstracted from plane P_1 , this means new operations or actions on plane P_2 will be added to those of plane P_1 from which the required information was abstracted. Consequently, reflective abstraction is necessarily *constructive* and *enriches* with new elements the structures drawn from plane P_1 , which amounts to saying it constructs new structures. This explains why the concrete operations based on sensorimotor schemes are richer than they were and why the same is true of propositional or formal operations, which are themselves based on concrete operations. As operations on operations, they add new modes of composition (combinatorial ones, etc.).

But reflective abstraction is the general constructive process of mathematics; it has served, for example, to evolve algebra out of arithmetic, as a set of operations on operations. Cantor constructed transfinite arithmetic in the same manner; he put into one-to-one correspondence the sequence 1, 2, 3, 4, ..., with the sequence 2, 4, 6, 8, ... This generates a new number (\aleph_0) which expresses the "power" (a number) of the denumerable, but is an element of neither sequence. Present function theory constructs "morphisms" and "categories," etc., in the same manner, and this is also true for the Bourbaki with the "mother structures" and their derivatives.

It is thus a remarkable fact that the process of the construction of structures we observe in the sequential stages of development in children and in the mechanisms of equilibration through self-regulation (which result in this self-regulation through feedback of a higher order, which is a reversible operation) coincides with the constant constructive process used by mathematics in their indefinitely fruitful development. This is a solution to the problem of development which reduces to neither an empirical process of discovery of a "ready-made" external reality nor to a process of preformation or predetermination.

(a priori), which would also mean believing that everything is ready-made from the beginning. We believe truth lies between these two extremes, that is, in a constructivism which expresses the manner in which new structures are constantly being elaborated.

VIII CONCLUSION FROM PSYCHOLOGY TO GENETIC EPISTEMOLOGY

30 The theory we have outlined is necessarily interdisciplinary, and it involves, in addition to psychological elements, components belonging to biology, sociology, linguistics, logic, and epistemology. The relations with biology are obvious since the development of cognitive functions is a part of the epigenesis that leads from the first embryological stages to the adult state. From biology we essentially retain the three following points:

a There can be no transformation of the organism or of behavior without endogenous organizational factors, because the phenotype, although it is constructed in interaction with the environment, is the genome's "response" (or a response of the entire population's genetic pool, the individual genome being a cross section of the gene pool) to environmental "stresses".

b Conversely, there is no epigenetic or phenotypic transformation independent of interaction with environmental influences.

c These interactions involve continuous processes of equilibration or self-regulation, of which the equilibrium between assimilation and accommodation is an early instance. This also appears in sensorimotor, representative, and preoperational self-regulations, and even in operations themselves since they are anticipatory self-regulations and corrections of error which do not rely any more on the feedback from an error which has already happened.

The relations with sociology are also self-evident, because even if the origin of cognitive structures is in the general coordinations of action, they are also interpersonal or social as well as individual, since the coordination of the actions of individuals obeys the same laws as intra-individual coordination. This is not true of social processes involving constraint or authority, which lead to a socio-

centrism closely akin to egocentrism, but it is true in situations of cooperation, which are in reality "co-operations". One of the fundamental processes of cognition is that of de-centration relative to subjective illusion (see ¶ 8) and this process has dimensions that are social or interpersonal as well as rational.

The relations with linguistics would have very little meaning if linguistics were still defending positions like Bloomfield's, with its naive antimentalism. But we can adopt, in G. A. Miller's words, a position of "subjective behaviorism," and in linguistics proper, the contemporary work of Chomsky and his group on transformational grammars is not very far from our own operational perspectives and psychogenetic constructivism. But Chomsky believes in the hereditary basis of his linguistic structures, whereas it will probably be possible to show that the necessary and sufficient conditions for the construction of the basic units on which are founded the linguistic structures are satisfied by the development of sensorimotor schemes, and this is what Sinclair is working on at the present time.

The relations with logic are more complex. Modern symbolic logic is a "logic without a subject," whereas psychologically there exists no "subject without a logic." The subject's logic is undeniably poor and the groupement structures in particular are of little algebraic interest, except for the fact that related elementary structures do seem to arouse the mathematician's interest. But we must note that in studying the subject's logic we were able to formulate the laws of the four-group of propositional transformations INRC in 1949, that is even before logicians themselves began to look into it. On the other hand, present work on the limits of formalization, initiated with Godel's proof, will, more or less necessarily, orient logic toward a kind of constructivism, and in this light the parallel with psychogenetic construction has some interest. Generally speaking, logic is an axiomatic system, and in our context we must ask: An axiomatization of what? It is certainly not an axiomatization of the subject's conscious thought processes, because they are inconsistent and incomplete. But behind conscious thought are the "natural" operator structures, and it is obvious that, even though it can indefinitely surpass them (because the

productivity of axiomatics has no formal limit), they became the basis of logical axiomatization through a process of "reflective abstraction"

31 Finally, there remains the great problem of the relations between the theory of the development of cognitive functions and epistemology. When one adopts a static rather than a psychogenetic point of view and when one studies, for example, the intelligence of an adult or of subjects considered at a single level, it is easy to distinguish psychological problems (how intelligence functions or what are its performances) from epistemological problems (what are the relations between the subject and the objects, and whether or not knowledge of the former adequately attains the latter). But when one adopts a psychogenetic point of view, the situation is completely different because one is then concerned with the formation or the development of knowledge, and it is essential to consider the roles of objects or of the activities of the subject, those issues which necessarily raise all the epistemological problems. In fact, those who attribute the formation of knowledge exclusively to experience, in the sense of physical experience, and those who introduce the activities of the subject in the sense of necessary organization will orient toward different epistemologies. To distinguish, as we have done (§21), between two types of experience—one physical with abstraction beginning from objects and the other logicomathematical with reflective abstraction—is to make a psychological analysis, but one whose epistemological consequences are clear.

There are authors who fail to appreciate the interconnections between genetic psychology and epistemology, but this only indicates that they are choosing one epistemology among other possible ones, and that they believe their own epistemology is evident. For example, when Bruner tries to explain conservations by means of identities and symbolization based upon language and imagery, believing himself able to avoid operations and all epistemology, he is actually taking the point of view of empirical epistemology. At the same time he invokes an operation of identity without noticing that it implies others. In giving conservations a more operational explanation, and in supposing

that quantities call for a complex construction and not simply a perceptual activity, we *de facto* remove ourselves from empiricism in the direction of a constructivism, which is another epistemology, moreover, it is much closer to present biological trends, which underscore the necessity of constructive autoregulations.

If we turn now to the epistemological side, we discover that its trends also differ noticeably, according to whether it adopts a static or a historical and genetical point of view as is its natural internal tendency. When epistemology simply asks itself what knowledge is in general, it believes itself able to make abstractions without recourse to psychology, because, in fact, when knowledge is achieved, the subject retires from the scene. But, in reality, this is a great illusion, for all epistemology, even when it tries to bring down to a *minimum* the activities of the subject, makes implicit appeal to psychological interpretations. For example, logical empiricism attempts to reduce physical knowledge to perceptual states and logicomathematical knowledge to laws of an ideal language (with its syntax, its semantics, and its pragmatics, but without reference to transformational actions). Now, these are two highly conflicting hypotheses, first, because physical experience rests on actions and not only on perceptions and always supposes a logicomathematical framework drawn from the general coordination of actions (of such kind that the operationalism of Bridgman must be completed by that of Piaget!) Second, logicomathematical knowledge is not tautological but constitutes a structural organization drawn from reflective abstraction of the general coordination between our actions and our operations.

But, most importantly, it is impossible that epistemology is static in point of view, because all scientific knowledge is in perpetual evolution, including mathematics and logic itself [of which the constructivist aspect has become evident since the theorems of Gödel have shown the impossibility of a theory to be self-sufficient (complete)—therefore, the necessity of always constructing "stronger" ones, from whence finally the inevitable limits of formalization!]. As Natorp said in 1910 "science evolves continually. The progression, the method is everything."

a consequence, the *fact* of science can only be understood as *fact*. Only the *fact* is the fact. All being (or object) that science attempts to fix must again dissolve in the current of becoming. It is in the furthest removes of this becoming, and there only, that one has the right to say, It is (fact). Therefore, that which can and must be sought is 'the law of this process'." (p. 15)

32 These uncontested declarations are tantamount to stating the principle of our "genetic epistemology," that in order to resolve the problem of what is knowledge (or its diversity of forms) it is necessary to formulate it in the following terms: How does knowledge grow? by what process does one pass from knowledge judged to be ultimately insufficient to knowledge judged to be better (considered from the point of view of science)? It is this that the proponents of the historicocritical method have well understood (see among others the works of Koyré and Kuhn). These critics, to understand the epistemological nature of a notion or a structure, look to see first how they were formed themselves.

If one takes a dynamic rather than a static point of view, it is impossible to maintain the traditional barriers between epistemology and the psychogenesis of cognitive functions. If epistemology is defined as the study of the formation of valid knowledge, it presupposes questions of validity, which are dependent on logic and on particular sciences, but also questions of fact, for the problem is not only formal but equally real. How, in *reality*, is science possible? In fact, all epistemology is therefore obliged to invoke psychological presuppositions, and this is true of logical positivism (perception and language) as well as of Plato (reminiscence) or of Husserl (intuition, intentions, significations, etc.). The only question is to know if it is better to content oneself with a speculative psychology or whether it is more useful to have recourse to a verifiable psychology!

This is why, as all our efforts lead to epistemological conclusions (this was moreover their initial goal), we have founded an International Center for Genetic Epistemology, so that psychologists, logicians, cyberneticists, epistemologists, linguists, mathematicians, physicists, etc., may collaborate there, depending on the problems being considered.

This center, which has already published 22 volumes (and several others are in press), has therefore had as its goal, from the beginning, to study a certain number of epistemological problems seeking to analyze experimentally the psychological data necessary for the other aspects of the problem.

We have thus studied the interrelations of logical structures from the double point of view of their psychological genesis and their formal genealogy (with Grize, Papert, Apostel, etc.), which has permitted us to find a certain convergence between the two methods. We have examined the problem with what the great logician Quine ironically called the "dogma" of logical empiricism, that is to say, the absolute distinction between the analytic and the synthetic. After having declared that all these authors, being occupied with that question, have had recourse to *factual* data, we have put them under experimental control and have declared that numerous intermediaries exist between these two sorts of relationships incorrectly judged as irreducible.

We have also studied the problems of the development of the notions of number, space, time, speed, function, identity, etc., and have been able to bring to all these questions new psychogenetic data, while completely removing from them regard to epistemological conclusions, which are as far removed from the a priori as from the empirical, and suggesting a systematic constructivism. With regard to empiricism, we have above all analyzed the conditions for an adequate interpretation of experience, and have added to this result what a mathematician-philosopher has summed up in these terms: "Empirical study of experience refutes empiricism!" We have seen previously (§ 14) several of our studies on the role of learning.

In a word, the psychological theory of the development of cognitive functions seems to us to establish a direct, and even quite intimate, relationship between the biological notions of interactions between endogenous factors and the environment, and epistemological notions of necessary interaction between the subject and the objects. The synthesis of the notions of structure and of genesis that determines psychogenetic study finds its justification in the biological ideas of auto-

regulation and organization, and touches on an epistemological constructivism which seems to be in line with all contemporary scientific work, in particular, with that which concerns the agreement between logicomathematical constructions and physical experience

10. *Werner's Comparative Organismic Theory*¹

JONAS LANGER

The central theoretical issue is dialectical how does a developing organism change qualitatively and at the same time preserve its integrity? It is important to keep this dialectical formulation² well in mind because

¹ As a student of Werner, I naturally find it almost impossible to differentiate precisely between Werner's views and those I have come to hold. Moreover, it is impossible to mark off where Werner's contributions end and those of his colleagues and students at Clark University begin, particularly the contributions of Bernard Kaplan and Seymour Wapner.

Since the theory is a comprehensive one and the theoretical issues involved in this discussion are complex, the reader may find it helpful to have an outline of the sequence of topics:

- 1 Orthogenesis
- 2 Organismic Analysis
- 3 Comparative Analysis
- 4 Interaction
 - 4.1 Schemes and Schematizing Activity
 - 4.2 Progressive Constructivism
 - 4.3 Egocentrism to Perspectivism
- 5 The direction of Mental Development
 - 5.1 Formal Dimensional Coordinates
 - 5.2 Mental Level
- 6 Comparative Mental Development
 - 6.1 Precursory Acts
 - 6.1.1 Presentational Symbols
 - 6.1.2 Things-of-Action
 - 6.2 Transitional Acts
 - 6.2.1 Protosymbols
 - 6.2.2 Perceptual Intuitions
 - 6.3 Contemplative Acts
 - 6.3.1 Symbols
 - 6.3.2 Concepts
- 7 Concluding Remarks

² Dialectical is being used in the Hegelian sense that development is the synthesis of antitheses, here, transformation and conservation.

the term "development" itself has tended to focus theoretical and empirical attention upon one pole of the dialectical process—the nature of adaptive change—at the expense of considering the other—the nature of organizational stability. A theoretical synthesis of both is necessary to the comprehensive developmental understanding of the integrity that marks a whole organism while it is altering through an ordered sequence of change.

Any narrowing of the developmental conception to the investigation of change alone, must be distorting. It may lead to the misconception that development is the kind of anarchism where totally unrelated and radically discontinuous stages follow each other in sequence, or it may lead to the kind of historicism where new or modified behaviors are merely added on in continuous temporal order as the organism grows. The anarchic perspective misses the functional and structural integrity of organismic development. It may mistakenly imply organizational dissociation between different periods of life. Historicism assumes a continuous, ongoing organism. Consequently, it does not adequately examine how the current organization influences the development of subsequent new behavior patterns or the modification of old behavior patterns. As such, historicism fails to inquire into whether and how the ongoing organization is altered as a consequence of such acquisition or modification.

The dialectical nature of development also has implications for the persistent question of why does an organism that is well adapted at one stage ever progress to the next stage. Insofar as development is a dialectical pro-

cess and the question of motive is legitimate in this context it should apply to organizational stability as well as change. Motivational questions about progress seem to have two related sources. The first is a generalization from empirical work on the motivation for the local or short-term acquisition and modification of a delimited performance or behavior pattern. Many investigators believe it to be legitimate to ask questions of motive, like what is the drive, instinct, reward, and/or reason for a given behavior (cf. Peters, 1958). The second source of motivational questions seems more theoretical. It is the view that development is nothing but the continuous, gradual, quantitative acquisition and slight modification of small bits of behavior over time (e.g., Bjou and Baer, 1961; Staats, 1968). Taken together these two ideas suggest that each bit of behavior acquisition and modification must be motivated and therefore the accumulation of bits over time, called behavioral growth, must be motivated. However, functional questions of motivation are misdirected when the process under consideration is long-term psychological development. Then motivational questions as to why a new stage develops when the organism is already adapted at one level are no more appropriate here than to the rest of evolutionary biology. It makes as little scientific sense to ask what motivates the development of a new stage of cognitive organization as, for example, to ask what motivates the evolution of a new species or what motivates the evolution of mature respiratory structures in humans.

The dialectical formulation of long-term change suggests that development is composed of a sequence of universal stages of organization, that is, structures and functions. Each stage of organization is simultaneously directed toward maintaining continuity or stability and generating discontinuity or transformation. The fundamental thesis is that evolution is a synthetic process that interweaves two antithetical organismic tendencies: to maintain continuity in order to conserve one's integrity (survival and organizational coherence) and to elaborate discontinuity in order to develop (Langer, 1969, p. 89).

There is, on one hand, the tendency of organisms to *conserve* their integrity, whether biological or psychological in the face of variable and often adverse, external or internal conditions; the organism tends to maintain its existence as an integrated entity. There is, on the other hand, the tendency of organisms to *develop* towards a relatively mature state under the widest range of conditions; organisms undergo transformation from the status of relatively little differentiated entities to relatively differentiated and integrated adult forms (Weiner and Kaplan, 1963, p. 5).

ORTHOGENESIS

In order to characterize these two dialectical but concurrent tendencies within the growing organism, Weiner (1948) adapted the embryogenetic principle of orthogenesis and applied it to mental development.³ The orthogenetic principle asserts that development is a process of increasing differentiation and specification of the organism's relatively global organization, coupled with a process of progressive centralization and hierarchic integration of the more individuated systems so that progressive equilibrium is achieved.

Progressive *differentiation* and specification of the organization of rudimentary action systems, such as sensory and motor systems, is one major side to development. Functionally, primitive systems may be fused with each others so that they have no flexible operative relationship to each other but rather operate in a rigidly fixed or fluctuating fashion. Differentiation leads to progressively discrete yet internally integrated means of action and intended ends that function in a flexible and

³ In a recent work (Langer, 1969, Chap. 4) I have attempted to show that Werner's and Piaget's conceptions have, common major theoretical and empirical features that make up much of the contemporary organismic approach to development. The present chapter will not, however, refer to Piaget's relevant work because it is presented by Piaget himself in this book. Rather, this chapter will refer extensively to Cassirer's philosophy of symbolic forms because his contributions to the study of genetic epistemology have made a major and direct impact upon comparative organismic theory.

stable fashion in relationship to each other. Structurally, primitive systems have no definite boundaries but are diffuse in both internal character and external relationship to each other. Differentiation leads to progressive individuation into definite and well articulated part systems that are coherently related to each other.

Progressive *hierarchical integration* is the reciprocal of progressive differentiation and the other major side to development. The most advanced (differentiated, specialized, and internally integrated) systems functionally regulate and structurally subordinate less developed systems. The long-range, developmental result of concomitant differentiation and hierarchical integration is the progressive construction of a holistic organization where the most central and advanced action systems regulate the more primitive systems.

The dialectical tension between the tendencies to change and to preserve stability is expressed in three theoretical ideas that are central to the orthogenetic conception of development (Weiner, 1957)

1 *Discontinuity* Differentiation is a process of altering a relatively global organization into a more individuated whole.

2 *Continuity* Hierarchical integration serves to maintain the organism's integrity in the face of change over time. As a consequence, some forms of the organism's structures and functions are preserved by being subsumed by the more individuated systems that have developed, not all primitive systems are lost or altered in the course of developing competence.

3 *Synthesis* of these two antithetical tendencies. The organization of a new stage is a reorganization of the previous stage that combines both continuity and discontinuity. The total pattern is altered but still continuous with the previous pattern. (a) new structures and functions are dominant and hierarchically integrate or control others, (b) differentiation leads to specialization and newly individuated systems, and (c) primitive systems that are preserved operate differently due to increased centralization and their regulation by more differentiated and integrated systems (cf, Langei, 1969, pp 172-177)

Several strategic ideas about research flow from the orthogenetic principle. To begin to study development requires an initial conception, however tentative, of the ideal end state or most mature organization that the organism may achieve in the course of its life. The reason for this is that developmental change is not an unlawful flux but rather directed alteration. To study and understand processes of mental development requires inquiry into its epistemological goal (cf, Cassirer, 1957). A comprehensive explanation of developmental processes will therefore require a coherent view of *final determination*, that is, a well established conception of the mental end state toward which development is directed and which lends significance to the processes of change. A complementary strategy is to inquire into the organization that constitutes the original mental state of the organism and the source of *material cause* of all further development (cf Weiner, 1948). This means determining the self-regulatory rules of coherence and the self-generative rules of adaptation that are inherent to the organism's original functional structures, since these are the inherent rules of developmental transformation and construction. Furthermore, determining the nature of development (conservation and change) requires comparison of the transformed psychological state with its foundation. Finally, determining the form of organization that constitutes the original and most advanced mental stages of development provides the basis for both determining the form of the transitional stages and determining the organism-environment interactions that *logically imply* the transformative construction from stage to stage (cf Langei, 1969).

Two major types of theoretical analysis flow from the orthogenetic formulation of the dialectical process of development. First, the orthogenetic conception of functional and structural development leads to an organismic analysis. In addition, the generality of the orthogenetic conception leads to a comparative analysis of psychological phenomena in the diverse contexts in which development may take place (Kaplan, 1966). It is to a consideration of these two types of analysis that the next two sections are addressed.

ORGANISMIC ANALYSIS

We may now return to the functional question of what causes an organism that is well-adapted at one stage of organization to change. Insofar as a functionally equilibrated state of adaptation has been achieved it provides the basis for coherent stability even at a stage of primitive organization (cf Goldstein, 1939). When the organism's primitive instruments or means determine and satisfy the problems or ends dealt with, the organism is in a balanced, albeit primitive state of adaptation. In complementary fashion, when the organism's primitive adaptive ends determine the instruments or means that are required, then the organism's rudimentary systems of action are adequate and the organism is also in a balanced state. Both means-ends relationships imply coherent organizational stability and do not provide the functional conditions that would generate directed change.

The probability is exceedingly small that a living organism is in perfect and total functional equilibrium. Indeed,

when one examines the developmental changes in means-ends relationships one observes the effects that newly emerging goals or ends have on the formation and restructurization of biopsychological equipment and the effects which in turn such newly formed equipment has in the determination of biopsychological ends (Werner and Kaplan, 1963, p. 7).

In particular, it is to be expected that the organism's primitive means and ends, such as its sensorimotor means and ends, are rarely equilibrated perfectly.

stability of behavior requires a flexibility of response in order to preserve the functional equilibrium of the organism in the face of mutable situations (Werner, 1948, p. 55).

But flexibility is not a characteristic of primitive systems of action. This suggests that primitive means and ends are never completely sufficient (adequate) or satisfying (adaptive). This is the functional disequilibrium that is necessary for means-ends reorganization.

wherever functional shifts occur during development, the novel function is first executed through old, available forms, sooner or later, of course, there is a pressure towards the development of new forms which are of a more function-specific character, i.e., that will serve the new function better than the older forms (Werner and Kaplan, 1963, p. 60).

Or a previously subordinate functional system acquires regulative control.

a reorganization of processes conditioned either by the introduction of a new function, or by a change of dominance of function in a given process-pattern (Werner, 1937, p. 353).

When the organism develops, the more primitive systems are not necessarily lost but become relatively less important and salient in the more advanced functioning of the organism. They are used less and their efficiency may deteriorate as more sophisticated systems become more dominant in the organism's life.

lower levels of functioning (both in terms of means and of ends) are subordinated to more advanced levels of functioning, they may come to the fore again under special internal or external conditions, for example, in dream states, in pathological states, under intoxication by certain drugs, or under various experimental conditions. They also, and characteristically, may come to the fore when the organism is confronted with especially difficult and novel tasks. In such cases one often finds a partial return to more primitive modes of functioning before progressing towards full-fledged higher operations, we may refer to this tendency as a manifestation of the *genetic principle of spirality* (Werner and Kaplan, 1963, p. 8).

Spiral development means that

The organism at times seems to retreat from a locus of maturity which it has already attained. Temporarily such a retreat may look like an abandonment. It would be abandonment if it continued on one tangent. The course of development, however, being spiral, turns back toward the point of departure,

and it does not return precisely to this point. It returns to the same region but at a higher level. The neurological result is an interwoven texture which expresses itself in progressive patterns of behavior. The unity of the ground plan of the organism is preserved. It is a process of reincorporation and consolidation (Gesell, 1946, p. 317).

The genetic principle of spatiality assumes that *analogous functioning* is one of the most general laws of development. Functional analogy between stages and systems of action implies that more primitive stages and systems are the primary sources or precursors of more advanced stages. It is clear that Werner's conception of functionally analogous processes is that of a fundamental law of development which informs the theoretical and empirical search for stages. This has been worked out in the greatest detail by Werner (1948) for the processes of relating, grouping, abstracting, generalizing, and representing, which make up concept formation.

There are, for example, three genetically parallel levels of establishing relations that involve analogous processes. Primitive, concrete "relating" is sensorimotor in form. Brightness transposition in chickens is a good example of the ability to establish sensorimotor relations.

When two areas of grey are united in a brightness configuration and acquire different functional values (+ and -) with respect to the food-seeking activity, we may safely assume that the animal has constructed a relationship on a sensorimotor level (Werner, 1948, p. 217).

According to Werner, one of Koehler's experiments with apes is a particularly apt demonstration of the concrete relations that can be constructed by sensorimotor activity. In order to rake in a distant object, a chimpanzee was provided with two bamboo rods, neither of which was long enough to get the desired object. The diameter of one rod A is smaller than that of B and can be fitted into B to make a long enough rod. If rod A must be pushed into B and B must be held steady so that A will fit in, then A is the active and B the passive rod. After having solved this problem through sensorimotor manipulations,

rod A was taken away and replaced with a third rod C whose diameter is larger than B. This requires that the chimpanzee act on the basis of (1) the relationship between (and not the absolute) sizes and (2) the relationship between (and not the absolute) active and passive elements. Upon sensorimotor inspection of the rods the chimpanzee solves the problem immediately.

"Relating" as a predominantly perceptual activity may proceed from simple to more complex levels. In one experiment (Werner, 1948, p. 220) children were presented with a card on which is presented four lines of a given size proportion. The task is to select other cards that show four lines with the same size proportion. Children can perform the task at a younger age if the lines are presented as a definite figure (see A) rather than as separate parts (see B).

Constructing relations at the most advanced level involves the formation of explicit abstract rules. Most often these rules are expressed linguistically, although they may involve even more abstract logical and mathematical forms. This would be the case if the preceding problem of relating lines were expressed and solved on the basis of a rule articulating the metric relations. It is Werner's central genetic hypothesis that even the construction of such abstract relations develops out of—and is a transformation of—concrete perceptual relations.

Two separate phases are often observable in the thought processes of comparison. The first is the formation of a perceptual relationship—the relation between two parts is grasped in a certain configuration. The sec-

ond is the derivative abstract form of the relationship as expressed in a verbally constituted judgment (Werner, 1948, pp 221-222)

The dialectical thesis serves to remind us of the organism's stable organization and therefore the central importance of structural considerations in the understanding of development. The assumption is that even in their initial infantile states, all organisms are organized and have some degree of competence. This organization provides the basis for acting. Its functional structures determine the range of conduct available to the organism and consequently the types of interaction with its environment that are open to it. It is obvious, for example, that a verbal environment cannot stimulate a verbal response from a newborn baby. The range of conduct and interactions therefore progress as the organization develops.

Now the organism's organization is composed of many parts or systems, such as those for locomotion, vision, and thinking, which have different characteristics. When these parts are in structural equilibrium, both within and between parts, they form a coherent whole and change will not occur (cf von Bertalanffy, 1933). But the probability of total structural (part-whole) equilibrium may be assumed to be just as small as the probability of perfect functional (means-ends) equilibrium. Consequently, structural change is always expected.

Wherever there is life there is growth and development, that is, formation in terms of systematic, orderly sequence (Werner, 1948, p 55).

In particular, it is to be expected that the organism's primitive structures are rarely equilibrated perfectly. For example, the young infant cannot reach for objects he is looking at and desires to grasp. More integrated structures are required for this coordination. This is the type of adaptive disequilibrium that is necessary for part-whole reorganization (cf Langer, 1969a). Eventually, more integrated structures develop, such as those requisite for efficient hand-eye coordination.

COMPARATIVE ANALYSIS

Much of the richness of the orthogenetic approach is provided by the comparative analysis of evolutionary change, whether found within a line or direction of development or between lines of development. That is, comparison may be within species evolution (phylogenesis), long-term individual development (ontogenesis), short-term individual development (microgenesis), societal development (ethnogenesis), and psychopathological development (pathogenesis). Comparison may also be made between domains.

the psychology of the individual and of the human race, animal and child psychology, psychopathology and the psychology of special states of consciousness—all these can be approached from the genetic standpoint. The final procedure of a comparative developmental psychology is to compare the results gained from work done in the specialized fields, and from the comparison to derive developmental laws generally applicable to mental life as a whole (Werner, 1948, p 5).

Two early developmental conceptions, those of Hobhouse and J. M. Baldwin, were especially significant in the formulation of the comparative approach. Hobhouse's (1901) comparative focus was upon the phylogeny and ontogeny of mental activity. He delineated six means of acting that become progressively available within phylogenesis. The first and most primitive is the *reflex* or blind, mechanical reaction of a preformed structure to a sensory stimulus. The next three means of acting that evolve beyond reflexes become increasingly dependent upon interactive experience. The second means of action is *trial and error*. It permits the organism to call upon a variety of reactions when an obstacle is met, until the situation is changed or the organism is unable to master it. As a consequence, for example, a paramecium may learn habitual modes of response. The third means, that of *assimilation*, is the adjustment of the organism's action to suit its needs such that modification of behavior is possible in the future. Here Hobhouse refers to Lloyd Morgan's experiment in

which chicks learned to discriminate between bitter and agreeable food so that they no longer pecked at the bitter food. The highest means of acting that is directly dependent upon experience is *practical judgment*. Different objects may be related in concrete experience or judgment, such as a chimpanzee's use of a stick as a tool with which to obtain a banana that is out of reach. The fifth means is *conceptual thought*, this means of acting is not dependent directly upon experience. It is a means of expressing explicit relations which is free from perception. It is the way in which knowledge, tradition, and culture are learned and used. The most advanced means of mental activity that evolves in phylogensis is *analysis* by logical operations, which involves rational, logicomathematical systems.

These six means of activity characterize the direction of mental development within both phylogensis and human ontogenesis. Hobhouse made it clear, however, that there were differences between phylogeny and ontogeny. The development of these six means of acting is obviously not a characteristic of the ontogeny of all species. The two most advanced means, conceptual thought and logical analysis, only evolve in human ontogenesis.

Baldwin's (1915) comparative focus was upon the relationship between the evolution of mental life in human ontogenesis and ethnogenesis rather than phylogensis. This led him to establish the discipline he called *genetic epistemology* or how "thought or experience makes to render reality" by comparing the progressive "stages of thought" that evolve in ontogenesis and ethnogenesis so as to construct "a natural history of interpretation itself." Although Baldwin argued that there is parallel "movement in the internal organization of thought and values" between human ontogeny and ethnogenesis, he maintained that it is ontogenesis that gives ethnogenesis "its vital impulse and its progressive 'uplift'."

Baldwin divides human ontogenesis into three progressive stages of interpretation. The first is the *prelogical* stage where the child's mode of action is "intuitive" and "quasi-discursive" or quasi-linguistic. The child makes no distinction between the subjective and objective factors in his experience. He accepts

"the reality of the datum" of experience. Thus knowledge in the prelogical period is pragmatic and presentational "a meaning of immediate presence and intuition." The interpretative mode of action at the next, the *logical*, stage is "discursive" or linguistic. Imaginative, esthetic schemes are used to unite thought (mediated interpretation of reality) with "the singular and the immediate." The person's imagination projects "its schematic and tentative readings" upon the environment. These imaginative projections have "the character of assumption, proposal hypothesis." Therefore all imaginative interpretations "have the force of possibility and probability" such that "reality is embodied in all sorts of 'as if' construction." But the person now begins to use verification procedures in order to assess the validity of his imaginative assumptions. This leads to the logical processes of judgment, reasoning, and implication that determine "what is to be accepted as real." At the highest, *hyperlogical* stage of ontogenesis "Consciousness achieves a freeing from logic as before she worked to secure the freeing of logic." Now the interpretative mode of action becomes esthetic contemplation which "erects into postulates its ends, values, and goods."

Baldwin hypothesized that the ontogeny of subjective (individual) interpretationism is paralleled by the progressive construction in ethnogenesis of objective (societal) embodiments of interpretation "in laws, rites, customs, sanctions." He therefore proposed three stages of cultural evolution that parallel the ontogenetic stages of interpretation. At the prelogical stage, the group's interpretative mode of action is mystical and takes mythical and religious forms. At the logical stage the mode of action is speculative, taking scientific and critical forms. The interpretative mode of action is transformed into "aesthetic contemplation" at the hyperlogical stage and takes the form of advanced philosophical theory.

Although important in their own right, Hobhouse's and Baldwin's comparative formulations do not fully meet the criteria for a formal theory of development, namely, that the assessment of change should not be bound temporally or in content, output, and value (see the section on The Direction of Mental Development). Werner's formulation

of formal coordinates provides the kind of theoretical dimensions that are required in order to make a purely formal comparative analysis within and between directions of evolution. Also, Werner extended the comparative analysis to include pathogenesis and microgenesis as well as phylogenesis, ontogenesis, and ethnogenesis.

Consider first an aspect of perceptual development. The comparative coordinates permit a purely formal analysis of the genetic level of perception and its change within and between ontogenesis, pathogenesis, and microgenesis. To this end a number of studies summarized by Werner (1957), have investigated form perception on the Rorschach test. If we rate undifferentiated, diffuse, and amorphous percepts as developmentally low while we rate differentiated, articulated, and well-integrated percepts as developmentally high, then the findings may be outlined as follows:

1. **Ontogenesis.** There is a significant and continuous shift from low to relatively advanced responses from the age of 3 to 10 years.

2. **Pathogenesis.** Four groups were tested. Their status was ordered in terms of pathology from the most severe regressives (hebephrenic and catatonic schizophrenics) to paranoid schizophrenics to psychoneurotics to normal adults. Again there is a clear progression from low to high responses, with the percepts of the hebephrenic and catatonic schizophrenics paralleling those of the 3- to 5-year-olds and the percepts of the psychoneurotics being intermediate between the 10-year-olds and normal adults.

3. **Microgenesis.** (a) Rorschach cards were presented for 0.01 second, 0.1 second, 1 second, and 10 seconds to four independent groups of normal adult subjects, respectively. There is a clear progression from low to high percepts. (b) The same exposure times were used with four independent groups of hebephrenic and catatonic schizophrenics. Their responses were not very different from the normal adults at the 0.01 second exposure time. But unlike the normals their responses evidenced no microgenetic progress.

Now consider an aspect of the comparative development of concepts, specifically that of time concepts. One general hypothesis is that

all primitive time cognition is egocentrically tied to the concrete, affective, and pragmatic aspects of the subject's conduct—it has the "concrete and affective character-of-action." One of the examples that Werner (1968) presents from ethnogenesis is that of the system of dividing up the day constructed by Uganda tribesmen who raise cattle. Their temporal scheme is based upon, and consists of, the order of the day's work events, such as milking time, watering time, and home coming time for the cattle. Primitive ontogenetic and pathogenetic cognition of time is also based upon a fusion of concrete acts and affective desire. One of the ontogenetic examples cited by Werner is that of a 6-year-old boy who pointed to different parts of the sky, saying "That's where the day comes out, and there, farther along, is the night, and right up at the top is Christmas day." Some of the pathogenetic examples that Werner analyzed follow:

Time, says one schizophrenic, falls together like a pack of cards. Another schizophrenic's experience of time during his quiet phase differed from his temporal experience during the phase of terrible anxiety. In the calm phase time moved on with great rapidity, ten months were as one. In the anxious phase, on the contrary, events hung motionless in a temporal vacuum (Werner, 1948, p. 190).

Head describes aphasiacs who, following a loss of the abstract schema, employed a concrete time-of-action. For instance, one patient had a concrete qualitative time scale made up of dominant movements in the succession of daily events: "Then, when you eat," "Then, when we arrive there," etc. (Werner, 1948, p. 190).

So far this comparative analysis of perceptual and conceptual development, as well as Hobhouse's and Baldwin's comparative analyses, focused upon the parallels within and between evolutionary domains. A thorough comparative analysis cannot afford to neglect the crucial differences, however.

For all practical purposes one may speak of a principle of parallelism: development in mental life follows certain general and formal rules whether it concerns the individual or

the species. Such a principle implies that, apart from general and formal similarities, there do exist specific material differences in the comparable phenomena (Weiner, 1948, p. 26).

These parallels must be taken as such, as merely indicating a similar mental structure in a general and purely *formal* sense. In a particular and *material* sense, there will be irreconcilable differences (Weiner, 1948, p. 26).

While it is obvious that there are particular content differences in comparable mental achievements, it seems equally clear that there must also be general formal differences in the social and psychological processes that underlie such achievements. Indeed, Weiner (1948), for example, details three basic differences between comparable primitive stages of ontogenesis and ethnogenesis. First, the young child is growing and his whole mental life is in the process of change. Adults in preliterate societies are fully developed and their mental life is relatively "fixed in tradition." Second, the child develops "out of his child's world into an alien world of adults." What he becomes is therefore greatly "the result of an interaction between these two worlds." By contrast the psychological world and status of an adult in a preliterate society is fairly permanent. Third, the child's "social pattern" of functioning is not well organized and formed while the social pattern of the adult in a preliterate society is well established. These fundamental differences do not negate the possibility of formal similarities and genetic parallels. But they also do not merely reflect trivial variations in the particular content of formally similar mental phenomena. Rather, there are also general formal differences in the organization of mental life at comparable primitive stages of ontogenesis and ethnogenesis.

INTERACTION

The organismic and comparative analyses suggest that all organisms are born with a minimal set of species-specific functional structures which permit them to interact with the environment in order to incorporate experience and stimulation, otherwise they

would not develop. This is the basis for the root organismic metaphor of interaction (Pepper, 1942). The organism actively takes in and digests environmental properties. The consequences are physiological and/or psychological development. It is obvious that physiological structures can only assimilate those environmental properties for which it has appropriate physiological organs. Similarly, psychological structures can only assimilate that experience and information for which it has appropriate mental systems. Thus it is the organism's organization that selectively determines the character of its interaction and the significance of its experiences. These experiences, in turn, feed back upon the functional structures which were the original source of the interaction. In ways that are still little understood, such feedback eventually leads to the qualitative alteration of the organization of one stage into the next more advanced stage.

This is the *material cause* of development: the organization of preceding stages logically implies but does not contain the organization of subsequent stages. Since the organization at each stage is different from that of other stages, the organism's interactions with its environment change in the course of life. When these interactions are not disruptive, the conditions are propitious for the organism to remain in equilibrium and its organization will remain stable. When the feedback from these interactions perturb the organism, then the disequilibrating conditions necessary for change are present and the probability of functional and structural reorganization increases (Langer, 1969a).

The key to the process of development (stability and change) is interaction. The environment is the scene or object of the organism's actions and development while the organism is the actor or the subject in this scene. Consequently, the organism is not merely a reactor to the environment, but an operator upon its *Umwelt* or scene (von Uexküll, 1934). The analysis of development therefore requires investigating the lawful changes in actor-scene ratios (cf. Burke, 1945) or subject-object relations (Werner, 1948) that occur in progressive or regressive evolution.

At this point we need to introduce a further distinction. This is the difference be-

tween the form and the content of acts and their products—mental experiences, achievements, and development. The interaction that results in the person's acts and their products is, of course, a composition of organismic and environmental factors. The role of the organism's functional structures is mediated by its schemes of interacting (cf. Langer, 1969). These functional structures determine the *form* of schematizing activity and consequently the form of interaction with the environment. Schematizing progressively constructs the forms of the organism's products including its own development. The *content* of the organism's interaction is more directly the result of the physical and social environment. The role of the environment's functional structures is mediated by patterns of stimulation. Stimulation provides much of the content upon which the organism acts and, consequently, greatly determines the content of the organism's achievements and development.

Schemes and Schematizing Activity

The concept of the scheme or schema⁴ and schematizing activity has become such a central idea in current theories of cognitive development that it would do well for us to dwell briefly upon its meaning. In his *Dictionary of Philosophy and Psychology*, J. M. Baldwin notes that a schema is a product according to Kant. It is a product of the transcendental imagination which through its exercise gives generality to sense experience and particularity to thought conceptions. A schema is also a mode of constructing or a formula for synthesizing. As a mode or a formula, it is a general rule that guides mental activity. As embodied in a characteristic form, a scheme is the particular mental product of this rule of action. For example, the schema of quantity is number and the schema of substance is permanence in time.

The more contemporary usage of schema was introduced by Head (1926). Head points out that Piaget accepted Hughling Jackson's

⁴ We cannot deal here, with the useful distinction introduced by Piaget between an operative scheme (e.g., conceptual conservation) and a figurative schema (e.g., perceptual constancy). Rather, we are using the terms synonymously and in a fashion that corresponds more closely to Piaget's use of *scheme* than *schema*.

hypothesis that, intellectually, speech disorders are failures to produce propositional statements. Piaget made an analytic distinction between the construction of thought (the preliminary to any symbolic expression) and the formulation of speech (which underlies the executive process of verbal production). Thus he distinguished between the psychological schemata that make up thought from the grammatical schemata or rules for its formation in words.

Head extended this usage of schema to the hypothesis of a general bodily "postural appreciation" or "dispositional system" of standards "against which all subsequent changes in posture are measured before they appear in consciousness." This schema or model is a constantly changing standard and record of the body's movements in space.

By means of perpetual alterations in position we are always building up unwittingly a model of ourselves, which is constantly changing. Every new posture or movement is registered on this plastic schema and the activity of the cortex brings into relation with it each fresh group of afferent impulses, evoked by a change in the position of the body (p. 488).

Thus Head's concept of schema included both the process of "schema building"—of schematizing activity—and the product of this activity—the "schema built."

The main point is that schemes have both functional and structural aspects. Functionally, schemes are self-constructive; these self-constructive powers serve to organize one's experience into percepts and concepts. Thus schemes are rules for the cognitive organization and satisfaction of interests, attitudes, and needs. Structurally, schemes are the products or representational forms of knowledge, attitudes, and needs, which are constructed by their own active schematizing operations. They are the "stuff" of cognition. (For further theoretical implications of the concept of schemes and schematizing activity see Langer, 1969, pp. 169–172.)

Progressive Constructivism

Weiner and Kaplan (1963) maintain that the course of development is marked by a ratio shift in interactive dominance from the

Table 1 Diagram of Developmental Transformations

Organism-Umwelt Relationships			Means-Ends Relationships
I Tropistic-reflex actions	to	Stimuli	Biophysical and biochemical transmission culminating in stereotyped reaction patterns of parts of, or whole, organism
II Goal-directed sensorimotor action	upon	Signaled things	Species-specific behaviors and individually learned patterns of response ("habits"), formation of signals (mammals), "natural" tool usage (apes), all predominantly in the service of biological ends
III Contemplative knowledge	about	Objects	Construction of tools and formation of symbols in the service of knowing about and manipulating the environment

scene to the actor as they have outlined it in Table 1. At primitive stages of development the scene or psychological environment is the prime initiator of interaction. Although the organism's functional structures determine the form of its conduct, it is still a relatively passive reaction to environmental stimulation. Progressively, at more advanced stages of development, organisms become the prime initiators of interaction as well as the determiners of the forms of their own conduct in the interaction. In this sense, the actor's behavior has become relatively spontaneous, self-generated action upon the environment. The organism becomes increasingly sovereign in initiating and determining the character of its own actions, and it increasingly molds or constructs even the content of the scenes to suit its own needs and goals.

An interesting symptom of the developmental shift in dominance in the actor-scene ratio is reflected in the ontogenesis from naive acceptance to critical appraisal of events. The stages of this development were first worked out by Bruner (and are reported by Bruner, 1933). They have been essentially replicated (Schwartz and Langer, 1967, Langer, 1969a) with respect to the evaluation and handling of an impossible task. The observed ontogenetic shift is from (1) an initial naive credulity and acceptance to (2) criticalness and rejection to (3) a final criticalness coupled with either an attempt to rectify the situation or with amusement.

Egocentrism to Perspectivism

The developmental shift in dominance from the biophysical press of the scene to the constructive activity of the subject is marked

by progressive differentiation of primitive egocentric interactions. Egocentric interactions are globally fused, that is, the organism does not discriminate between himself (his status as a subject, his acts, his experiences and his feelings) and the environment (its status as an object, its behavior, and its stimulation).

the young child's acceptance of dreams as external to himself, the lack of differentiation between what one dreams and what one sees, as is found in psychosis, or in some nonliterate societies, the breakdown of boundaries of the self in mescaline intoxication and in states of depersonalization—all of these betoken a relative condition of genetic primordality (Werner, 1957, p. 127).

Werner (1948) cites the case of a paranoid schizophrenic who is fearfully observing doors swinging back and forth. This leads him to exclaim, "The door is devouring me!" Werner analyzes this behavior.

Affect has once more become a factor in the configuration of the surrounding world. This occurs not in the sense that the world of things become invested with an especially strong overtone of emotion, but rather in the sense that affect actually forms the world itself. The properties of things cease to be entirely objective, geometric, and "out there." Actually they acquire and express a much greater "depth" and inner significance (1948, p. 81).

Differentiation of primitive interactions in progressive development is accompanied by

increasing integration of the actor with his scene

Higher types of action are formally characterized by an interaction of personality with an outer discrete world, both polar elements being relatively self-subsistent (Werner, 1948, p 191)

This means that the subject has relatively greater understanding of his environment and its influences on him and his effects on it. It also means increasing perspective on the part of the subject. He can increasingly sympathize with, empathize with, and adopt the perspectives of others as well as his own, and he can increasingly integrate all these to form a coherent basis for his own conduct.

Increasing subject-object differentiation involves the corollary that the organism becomes increasingly less dominated by the immediate concrete situation, the person is less stimulus bound and less impelled by his own affective states. A consequence of this freedom is the clearer understanding of goals, the possibility of employing substitutive means and alternative ends. There is, hence, a greater capacity for delay and planned action. The person is better able to exercise choice and willfully rearrange a situation. In short, he can manipulate the environment rather than passively respond to the environment. At developmentally higher levels, therefore, there is less of a tendency for the world to be interpreted solely in terms of one's own needs and an increasing appreciation of the needs of others and of group goals (Werner, 1957, p 127).

The findings of three sets of perceptual studies document the shift in actor-scene ratio from egocentrism to differentiated perspectivism. The first set deals with the perception of self-object relations, the second with the perception of the self, and the third with the perception of the scene.

The paradigm for experimental inquiry into self-object relations involves investigating the developing relation between perception of body and object positions (Wapner and Werner, 1965, Wapner, 1969). Subjects were placed in a tilted position in a dark room. Then they were required to indicate where a

luminescent rod must be placed in order to locate their own position (self) vis-à-vis that of the true vertical (object). The angular separation between apparent body and apparent object position is used as an index of their perceptual relation for the subjects. There is a shift from perceiving body and vertical positions as relatively next to each other (from age 6 to 13) to seeing them as increasingly separate (from age 13 to 18). These data may be interpreted as measuring aspects of the ontogenetic shift from global syncresis to analytic discreteness in self-object relations.

The paradigmatic comparative analysis of progressive, arrested, and regressive shifts in self-perception involves experiments on apparent body size (Wapner, 1964, Wapner and Werner, 1965). In one series of studies the focus was on apparent head size as indicated by subjects placing their index fingers on a rod in front of them while keeping their eyes closed. The comparative findings may be summarized as follows:

1. There is an ontogenetic shift from great overestimation at 5 years to a relatively minor degree of overestimation by 18 years.

2. The natural ontogenetic articulation of the boundary between the self and the world may be simulated experimentally. For example, if one side of the child's head is touched, then his size estimate of the articulated but not the untouched side diminishes.

3. Retarded children overestimate their head size more than normal children.

4. Schizophrenics overestimate their head size more than normal individuals of the same age.

5. Adults given LSD-25, a drug assumed to induce regression, overestimate more than adults given a placebo.

6. Increasing overestimation accompanies old age.

Together these particular data are consistent with the more general comparative hypothesis that there is a shift from diffuse self-perception at primitive stages to an articulate self-perspective at advanced stages of development.

Experimental inquiry into the developmental shifts in the status attributed to objects in self-object interactions takes the following kind of form (Wapner, 1969).

Subjects are presented with a luminous \times (two lines at right angles to each other) in a dark room. They are seated in a chair that is tilted 45° to the right. Consequently, when asked what algebraic sign the object is they can either respond that it is a plus or a multiplication sign. The hypothesis is that egocentric perception will lead to the judgment that it is a plus sign because that is consonant with the subject's own position of viewing the object. On the other hand, a more perspectivistic outlook will tend to assess the object in terms of its context in the total field and relatively play down one's own subjective orientation. The ontogenetic findings from third-, fourth-, fifth-, and sixth-grade children confirm the hypothesis. Third graders give the highest frequency of "plus" responses and sixth graders the highest frequency of "multiplication" sign responses.

In sum, these three findings indicate the progress in perceptual judgments of the self, the scene, and their relation in self-object interactions. Primitive stages are dominated by egocentric constructions of the actor-scene ratio, whereas more advanced stages are marked by the construction of perspectivistic ratios that seek to take into account and integrate multiple viewpoints.

THE DIRECTION OF MENTAL DEVELOPMENT

Werner made many deep changes in his theory of mental development over the 40-year span of his writings. The most profound trend was a progressive movement away from a temporal formulation that would only fit the growth trends of individual life cycles, and a movement toward an ever more logical and abstract formal characterization of progressive, arrested, and regressive development that could account for evolutionary mental change wherever it occurs, whether in the field of phylogenesis, ethnogenesis, ontogenesis, microgenesis, or pathogenesis. The aim was to avoid being forced into the assumption that development had taken place just because the organism under consideration (animal, man, patient, society) had passed through a long period of time (Kaplan, 1966a).

This required conceptualizing primitive and advanced stages of development in formal terms that adequately cover the comparative

field of mental evolution. The aim was to establish dimensions of assessment that are (1) not temporally bound because chronological growth alone does not insure either progressive or regressive alteration, (2) not content bound because it is the form of the organism's actions and products that mark his mental development, (3) not output or achievement bound because a number of processes having different developmental status may lead to the same observed output by the organism (Werner, 1937), and (4) not value bound because the theoretical requirement is for objective rather than evaluative means of assessing change and stability.

Formal Dimensional Coordinates

Werner's (1948) orthogenetic formulation of development as the "increasing differentiation and centralization or hierarchic integration, within the genetic totality" was an initial step in this direction, providing a purely formal principle. On this basis, Werner further specified four formal sets of coordinates for the analysis of the genetic level of mental phenomena.

The central set of formal coordinates for the functional analysis of development is that of *syncretic* to *discrete*. Functional undifferentiatedness is especially marked by syncretic fusion of systems of action. Syncretism may obtain between subsystems within a system, such as emotional undifferentiatedness during infancy and early childhood (Bridges, 1931) and such as the perceptual fusion of sensory modalities in synesthesia (Werner, 1948). Syncretism may also obtain between systems, such as the affective and imaginal fusion implied in the confabulations of dream and hypnagogic imagery (Silberer, 1951). Syncretism is also a mark of functionally undifferentiated mental forms (e.g., the several meanings that may be fused in a dream image but not necessarily in a conscious thought) and functionally undifferentiated subject-object relations (e.g., egocentrism). Orthogenesis is marked by increasing functional discreteness or individuation of systems of action. Again, this is true for the functional relationship between subsystems within a system (e.g., the differentiation of various emotions and perceptual modalities during ontogenesis) and between systems (such as the differentiation of the affective and the imag-

mal) The same holds for mental forms (such as the relatively discrete significance of different conscious thoughts) and subject-object relations (e.g., the differentiation aspect of perspectivism)

The central set of formal coordinates for the structural analysis of development is that of *diffuse* to *articulate*. Lack of structural differentiation and centralization is especially marked by the diffuse organization of parts (individual systems of action) and their lack of integration with the whole (the totality of systems). Structural diffuseness may be between (1) parts or systems of action such as the "mass activity" of much of the newborn infant's behavior, (2) subsystems within a part or system such as the neonate's general use of his facial muscles, including those controlling the lips, when sucking, (3) parts of mental forms, such as the lack of articulation of the symbols and their referents in word realism (Vygotsky, 1934), and (4) characteristics of the actor-scene ratio, for example, as noted previously, the young child does not articulate well the boundaries between himself and the environment, resulting in relative overestimation of some of his body parts. Progressive structural "transformation of the diffuse into the articulated occurs as a dividing up, a progressive disjunction, of the whole into related parts" (Weiner, 1948, p. 54). In particular, structural articulation takes place between (1) parts or systems of action, such as the differentiated but integrated way in which different parts of the body are used in well executed sports play, (2) subsystems within a system, such as the muscles used in sucking efficiently, (3) parts of mental forms, such as the relative detachment of a symbol from what it refers to in conventional linguistic behavior, and (4) characteristics of the actor-scene relationship, such as the above noted progressive definition of body boundaries in development.

Two other sets of formal coordinates are relevant to the assessment of both structural and functional orthogenesis. These are the dimensions of *rigid* to *flexible* and *labile* to *stable*. At undifferentiated stages of development, mental organization is relatively rigid and yet unstable (Weiner, 1946). Differentiation, centralization, and hierarchic integration lead to increased plasticity while insuring new stability of mental organization.

Primitive conduct is rigidly bound to the organism's attitudes. Progressive development is marked by differentiation and hierarchic integration of attitudes so that the organism flexibly (1) attributes differential status—either objectivity or subjectivity—to its various acts and (2) shifts the dominance from one to the other attitude depending upon factors such as organismic needs and environmental demands.

Primitive conduct that is labile is characterized by fluctuation in the self-concept. For example, the young child may think that he and others are transformed in essence by wearing different clothes or by saying they are different animals (e.g., De Vries, 1969). Often his lability is expressed in playful creation of imaginary friends and in playful "splitting" of his own character into a good and a bad self (Weiner, 1948). The "good" self may scold the "bad" self, the "bad" self may transform itself into a "good" child, and so on. Development involves progressive stabilization of the self-concept so that the organism no longer acts as if it were being radically transformed or "split" in character but is a differentiated and hierarchically integrated whole. In human ontogenesis this means that the child's self-constructive activity is directed toward (1) differentiating himself as a stable, subjective entity that is discrete from others so that he feels and acts like a distinct individual and at the same time (2) integrating himself as a participant in, and member of his social order, thereby acquiring the same objective status as others. The most advanced forms of individuation involve the conception of oneself as a consciously active operator attributing the status of a relatively subjective character to the self, such as having internal, covert, and psychological character. At the same time it involves the conception of oneself as attributing a relatively objective character to other things, such as having external, overt, and physical character.

Mental Level

Consider for a moment what the utilization of these formal coordinates means for the comparative assessment of whether an organism is operating at a relatively primitive or advanced level. Such an assessment must include a consideration of at least three factors. The first consists of determining which *dimen-*

sional coordinates are relevant. The second is determining the *system of action* that produced the phenomenon to be analyzed. The third is the analysis of the *form* of the particular *mental operation* involved in the production of the phenomenon.

In order to make the point, it is necessary to recall some exceptional phenomena first, such as John Stuart Mill's writing philosophical treatises at 6 years of age and Mozart's composing music at 4 years. The systems of action that produced these phenomena are something like logical thinking and musical composition. And it could hardly be argued that the developmental level of the systems of action involved was primitive on any of the dimensional coordinates formulated by Werner. In terms of these systems of action, J. S. Mill and Mozart were obviously at advanced stages of development during their childhood, even though they were still at comparatively primitive levels of functioning in terms of their physiological and other aspects of their psychosocial development. This means that a given organism may be operating at many levels of development during the same chronological period of life. There need not be parallel rates of development of all the organism's systems of action.

Now let us recall some more typical phenomena. We are all used to observing rather primitive phenomena in adults in our society. For example, this author recently had to deal with an experienced paint salesman who could only mix paints absolutely by following a given formula and not proportionately by experimenting with the parts. In terms of Werner's formal coordinates, his paint-mixing behavior was rigid and diffuse even though he had spent much of his adult life at it. This is but one anecdote of primitive mental activity in literate adults in a Western culture.

Now consider some documented findings. Kohlberg (1968) reports that about two-thirds of adults in our culture reason at a relatively primitive level of moral judgment, that is, at stages 3 and 4 in Kohlberg's 6-stage scheme. Furthermore, Kramer (1968) presents longitudinal data which show that in some cases level of moral reasoning seems to temporarily slip back during late adolescence. The interpretation of such data is complex and subject to debate. Perhaps the system of moral reasoning actually regresses during late

adolescence to a more primitive stage. On the other hand, the data may mean that (1) the adolescent is more hierarchically integrated and can operate at many moral levels, or (2) these more primitive moral judgments are serving the purposes of another system of action, such as that of conventional mores, which is hierarchically subordinating the moral system, or (3) there is a conceptual syncresis between moral judgments and conventional mores that reflect initial attempts to differentiate and integrate these two forms of reasoning. Resolution of this question requires much additional data on subjects' abilities to appreciate, comprehend, and produce moral reasoning. But the major point is clear: the *potential* (rather than the *actual*) functional stage of an organism's system of action cannot be determined simply from observations of particular phenomenal manifestation of the range of the organism's capacities and of the cognitive structure of the systems involved. (For further discussion along these lines, see Kohlberg, 1968 and Turiel, 1969).

Finally, we should note Kohlberg's (1968) report that Taiwanese Atayals show the following development in their conception of dreams. Like children in our culture, they progress from the notion that dreams are concrete and external to the idea that they are imaginal and internal. However, Atayal adolescents, unlike adolescents in our culture, revert to an idea that dreams are concrete and external. Now it is clear that the Atayals develop advanced notions of dreams during late childhood. Then they seem to regress, perhaps like adolescents in our culture when they are reasoning morally. This would raise the same questions of further diagnosis we have just alluded to.

Before drawing this section to a close it is especially important to reinforce two points. First, in order to inquire into the processes underlying an organism's conduct and achievements it is necessary initially to diagnose adequately the level at which it is functioning. For example, if we presume that the normal human adult always operates contemplatively or logically, then we will misinterpret much of his conduct and profoundly misunderstand its etiology. We will fall into the same type of error if we presume that the behavior patterns of all animals are reactions to stimuli which are shaped by condition-

ing mechanisms regardless of the phylogenetic and ontogenetic status of the animals

The second point is that the ascription of a mental phenomenon to one of the stages is without prejudice to its value, whether moral, esthetic, or any other value. Ideally, any psychological phenomenon under scientific consideration should be classifiable by this taxonomic scheme. Its location at a given level is obviously only the result of the comparative organismic perspective underlying this scheme. Its location is therefore meaningful and scientifically useful only in light of this particular comparative organismic perspective, which seems so far to comprehend and tie together a wide range of phenomena, that is, its location has explanatory and heuristic value only within the present theoretical system. However, its location is by no means immutable, if there were a different developmental perspective that constructed a radically different taxonomic scheme, then that same mental phenomenon might be ascribed to a very different developmental location. Which location would be most adequate might then be crucially tested. Unfortunately, from the scientific point of view, radically divergent taxonomic schemes of mental development are not yet available.

The general idea to be drawn from all these considerations is that childhood, nonliterate, and schizophrenic activities are not assumed to be synonymous with primitive stages of development. Nor are adult, literate, and normal activities synonymous theoretically with advanced stages of development.

COMPARATIVE MENTAL DEVELOPMENT

As previously noted, Werner and Kaplan delineate three fundamental evolutionary transformations in the organization of mental activity and their constructed products (see Table 1). These three transformations in mental representation may be taken to reflect the three major stages in the progressive constructivism of biopsychological evolution. These stages form a hierarchy where the most advanced forms of mental activity that arise during the final, most mature stage integrate the more primitive forms that are their precursors.

Neither the theoretical boundaries between the three stages nor the formal criteria for

establishing stage boundaries were explicitly spelled out by Werner. Yet there is implicit order from the precursory stages of mental development to their final culmination in the stage of contemplative operations.

Three basic assumptions are made about the genesis of all mental activity. The first is that it is futile to seek the historical origins of mental operations in the absolute sense. A more appropriate theoretical and empirical strategy is to determine the analogous processes that underlie mental activity at different stages of evolution. This is the task of *genetic morphology* (Gesell, 1946). It requires formal descriptive analyses of the patterns of functioning underlying psychological activity at different stages of evolution so that they may be related developmentally and epistemologically. The second assumption is that analogous but lower-order patterns of functioning are prerequisite to the emergence of higher-order patterns of functioning. The third assumption is that lower-order functional patterns do not ordinarily drop out when higher-order patterns emerge (e.g., Halpern, 1965). Very often they are hierarchically integrated into the emergent, more complex organization with the higher-order functions dominating, centralizing, and regulating the lower-order functional patterns. In his epistemological analysis, Cassirer (1957) comes to much the same conclusion about the history of physics:

physical thinking has risen step by step to ever higher areas. Each higher stage of objectivization sets a limit to the preceding stage, but in this limitation it does not destroy the earlier phase, rather it embraces it in its own perspective (p. 477).

This means that primitive systems may continue to develop and that they are integrated in the form they attain during a given stage of development rather than the form they took in the stage in which they originated.

As far as human ontogenesis is concerned it is clear that man primarily passes through the two most advanced stages outlined in Table 1. Werner's developmental characterization of man therefore focused upon the extremes of these two stages in order to clarify the most primitive and most mature forms of functioning.

In advanced forms of mental activity we observe thought processes which are quite detached from the concrete sensorimotor, perceptual and affective type. In the primitive mentality, however, thought processes always appear as more or less perfectly fused with functions of a sensor-motor and affective type. It is this absence of a strict separation of thought proper from perception, emotion and motor action which determines the significance of so-called concrete and affective thinking. Concrete and affective thinking are therefore characteristic examples of syncretic activity (1948, p. 213).

Much less attention was given to formulating a consistent set of intermediate, transitional stages that comprehensively take into account the variety of mental developments. Instead the transitional stages were loosely united into a larger stage of intuitive or perceptual representation. This is not to imply that Werner completely neglected the taxonomic task of working out the transitional stages. However, his efforts along these lines were restricted to establishing transitional stages of specific mental activities, such as the intuitive construction of spatial concepts. Werner did not attempt to formulate precisely general transitional stages that, for example, simultaneously encompass the construction of the fundamental cognitive concepts such as space, time, number, and causality.

The orthogenetic relationship of the three major stages of mental construction is such that the most advanced contemplative systems hierarchically integrate the more primitive sensorimotor and intuitive systems, when all three systems have developed in an organism. It is highly unlikely, for example, that adult humans ever construct a pristine percept that is untinted by any contemplative operation. This means, however, that perceptual or intuitive representation is not only a stage of development but one of three parallel systems of action that may develop into the most mature (differentiated and hierarchically integrated) organization possible. Consequently, development may be schematized, according to Werner, as a three-branched tree like that in Fig. 1.

The parallel branch model is consistent with the idea of spiral development. This principle suggests parallel development be-

tween stages and systems of action from an initial state of egocentrism to a final state of perspectivism within each stage. The general theoretical hypothesis may be summed up as follows: Not only is there development *between* stages and systems of action (that may be measured along formal dimensions such as egocentrism to perspectivism) but parallel progress *within* any one stage and system of action (that should be measurable on the same dimensions). A major theoretical task that Werner began, then, is to work out the comparative development of each psychological stage and system of action from its most primitive manifestations to its most sophisticated forms. For example, with respect to perceptual representation, Werner hypothesized that

In both microgenesis and ontogenesis the formation of percepts seems, in general, to go through an orderly sequence of stages. Perception is first global, whole qualities are dominant. The next stage might be called analytic, perception is selectively directed towards parts. The final stage might be called synthetic, parts become integrated with respect to the whole (1957, pp. 127-128).

The theme that runs through this developmental analysis is that the human psychological world in particular is not a reflected reality that merely mirrors the physical and social environment. Rather, it is a representa-

tional reality or product that is constructed by man's means of mental action that serve to achieve his ends. These constructed products or representations are the core of human mental life. They are composed of two reciprocal schematizing aspects (Werner and Kaplan, 1963). One is the formation of symbols (ranging from the imaginal and gestural to the verbal and mathematical) that conceptualize, depict, refer to, and communicate cognized experience. The other is the formation of cognized experience, including feelings, percepts, and concepts, through representation. Throughout the presentation that is to come we will first present the general schematizing or representational activity central to each stage. Then we will consider the symbolic and objectifying functions that mark each stage. The strategic basis for this theoretical analysis is summed up by Cassirer:

With the dissection of phenomenal reality into presentative and representative factors, into the representing and the represented, a new motif is acquired which operates with increasing force and henceforth determines the entire movement of theoretical consciousness (Cassirer, 1957, p. 142).

Precursory Acts

Werner (1948, p. 59) contends that the classification of development on the basis of a content analysis "is quite inadequate for the analysis of primitive psychic events" because "primitive mental life reveals a relatively limited differentiation of object and subject, of perception and pure feeling, of idea and action, etc." The products of primitive mental constructions are basically global phenomena in which vital physiological, motoric, affective, and sensory processes are fused. In support of this contention, Werner summarizes the evidence from many studies on form discrimination in dogs. These studies show that their usual facility for form discrimination, such as between a circle and a triangle, is debilitated when the dogs' physical movements are restricted. The facilitative effect of physical movements in lowering visual recognition thresholds in adult humans (Miller, 1963; Dowling, 1965) provides reciprocal evidence.

Werner was particularly impressed by the dynamic character of primitive mental life.

The high degree of unity between subject and object mediated by the motor-affective reactivity of the organism results in a dynamic, rather than static, apprehension of things (1948, p. 67).

He cites phylogenetic evidence, such as the frog ignoring prey that does not move, and ontogenetic evidence, such as the neonate's greater responsiveness to suckable objects if they are moved suddenly. Werner (1948, p. 69) hypothesizes that it is the "dynamization of things based on the fact that the objects are predominantly understood through the motor and affective attitude of the subject" that underlies the lack of differentiating animate from inanimate events. This is why some inanimate objects will be perceived immediately as animate or expressing "some inner form of life." It is this immediate dynamic mode of mental activity that he called *physiognomic* in order to distinguish it from the more matter-of-fact, *geometric-technical* mode of cognition. The physiognomic mode of mental activity lies at the heart of subjective constructions, that is, the individual's mythical, magical, and esthetic cognitions, whereas the geometric-technical mode represents the direction that the individual's objective constructions take, that is, his physical, social, and logical cognitions. Synthesis of these two modes is characteristic of primitive mental acts and their products. Their differentiation and synthesis in contemplative operations mark the potential richness and creativity of mature mental acts and their products.

Werner extends his contention that primitive mental life is the global product of fused functions to the hypothesis that even the different sensory modalities are relatively undifferentiated at primitive stages of development. Consequently, a given stimulus, such as a sound, is more likely to evoke other impressions, such as color and warmth, rather than its corresponding auditory sensation. An example of such undifferentiated, *synesthetic* experiences, cited by Werner, is that of 3-year-old Bubi Scupins saying that "The leaf smells green" and "That [a lilac] smells awfully nice and yellow." It is Werner's hypothesis that such expressions are not the result of the young child's linguistic inadequacy but an "actual undifferentiated experience of sensa-

tion" It should be noted that an adequate ontogenetic test of this hypothesis has still not been devised. Werner further hypothesizes that

synaesthesia as a primordial form of sensory experience may reappear as a consequence of a pathologically conditioned primitivation (1948, p. 92)

Primitive concrete action is characterized by "*immediacy, limited motivation, and lack of planning*" (Werner, 1948, p. 191). Personal motives do not play a role in primitive action. Primitive action is "set in motion by vital drives on the one hand, and the concrete signals of the milieu on the other" (Werner, 1948, p. 194). This is true for much of animal and infant behavior. For example, animals learn mazes more rapidly when hungry and infants learn how to find objects more easily if it is rewarding.

Primitive mental activity lacks the specificity and direction that is the mark of abstract intentional planning. Werner cites C. Buhler's finding that infants are even unable to master a situation such as that requiring brushing away a cloth which has been laid on their faces. Only about 25% of infants at the age of 1½ months show any purposeful movements directed toward getting rid of the cloth, only about 50% of the movements are purposeful even at 4½ months, and the majority of purposeful manipulations become successful at the age of 7 months.

The uncoordinated, global character of primitive mental activity means that representation does not yet articulate "partial goals, the one following the other in succession. There is a single goal which can be realized only in the totality of the course of the action" (Werner, 1948, p. 201). Eventually this diffuseness gives way to the individuation of the global activity, with parts of the body acquiring specific functions. The same is true of global goals. As they become increasingly volitional and representational they involve a routine with subparts. Each subpart has relative independence from its predecessor so that the whole does not necessarily have to be run through in an unbroken, rigid, and stereotyped fashion. Central control is achieved so that parts no longer have equal value and nonessential acts are subordinated

to essential acts. As an example, Werner cites Zeigarnik's findings that the disruption of an activity is a much more vivid experience for children than adults and leaves a stronger memory impression.

Uncoordinated acts are marked by the lack of integration between different movements that will eventually become coordinated parts of a larger whole, for example, hand-eye coordination. Lack of well established "syntactic relation" between parts accounts for the greater difficulty that children have with classical problem solving tasks that require coordination between partial instruments and acts. Progressively, this rigidity of action gives way to a plasticity of the external character of action and the inner motivations and goals of the actor. Thus the child can increasingly modify his behavior flexibly to accord with his representational assessment of the situation in which he finds himself.

The immediate, presentational character of primitive action is most evident in the global, helpless, and noninstrumental movements of the neonate. The immediate, presentational character of primitive action is also apparent in the difficulty young children and chimpanzees have in dealing with problem situations that require circuitous behavior, such as extending a rake through bars beyond a desired object in order to haul it in. Such observations are important because perhaps the most striking indication that cognition is becoming representational and conceptual is the evolution of circuitous behavior since a "mark of the release of the subject from the domination of the concrete field is the extension of the action beyond the visibly given field" (Werner, 1948, p. 194). Werner cites the following evidence. Chickens (Révész, 1921) and sea gulls do not seek food that they have seen hidden while crows and jackdaws (Hertz, 1926, 1928) are more like higher vertebrates such as apes (Tinkelpaugh, 1928), who will search for and recognize food that they have perceived being hidden. The human infant only begins to search for and recognize an object hidden in front of him at about 9 months of age (Buhler, 1931) and shows some freedom of action to retrieve hidden objects at 13 months (Stern, 1930). Cassirer states the case for the immense epistemological significance of this developmental phenomenon for the construction of organized

mental life—for representation and conception—most elegantly

This act of recognition is necessarily bound up with the function of representation and presupposes it. Only where we succeed, as it were, in compressing a total phenomenon into one of its factors, in concentrating it symbolically, in "having" it in a state of "pregnancy" in the particular factor—only then do we raise it out of the stream of temporal change, only then does its existence, which had hitherto seemed confined to a single moment in time, gain a kind of permanence for only then does it become possible to find again in the simple, as it were, punctual "here" and "now" of present experience a "not-here" and a "not-now." Everything that we call the identity of concepts and significations, or the constancy of things and attributes, is rooted in this fundamental act of finding-again.

But here there is a demand that consciousness—contrary to its fundamental character, contrary to the Heraclitean flux in which alone it seems to subsist—shall step twice, in fact many times, into the same river. Transcending objective time and experienced time, it must seize upon a permanent and stable content and posit it as identical with its self. Identifications of this kind—even if they do no more than establish and postulate purely sensuous qualities—contain the germ and beginning of every form of concept formation. For the identity or similarity which we apprehend in two different and temporally separate impressions is itself no mere impression that is added to the others and simply embeds itself in the same plane with them. If something that is given here and now is taken and recognized as a "this,"—if for example it is recognized as a certain shade of red or as a tone of a certain pitch—we already have to do with a genuinely "reflective" factor (1957, pp. 114–115).

Presentational Symbols Even as they originate in the mental activity of the operating subject, symbols are not merely substitute signs that are originally learned as arbitrary and conventional labels for things. Rather, at first symbols inhere in and express or signal the thing-of-action construction of the objects they serve to determine, refer to, and represent.

For the analysis of sensory appearance showed that its very *appearing*, its presentation is impossible without an ordered and articulated system of purely representative functions.

Without the relations of unity and otherness, of similarity and dissimilarity, of identity and difference, the world of intuition can acquire no fixed form, but these relations themselves belong to the makeup of this world only to the extent that they are *conditions* for it, and not parts of it (Cassirer, 1957, p. 300).

Weiner and Kaplan (1963) hypothesize that the original ontogenetic situation out of which the representational function develops is what they call the *primordial sharing situation*. In this situation the human infant is "sharing" rather than "communicating" an experience (the object of reference) with another person, usually the mother. That is, the primordial sharing situation is a sensorimotor affective "pre-symbolic situation in which there is little differentiation in the child's experience between himself, the other (typically the mother), and the referential object" (p. 42). The precursory components for symbolization, however, are present. Together, the mother and child are sharing the same thing. What is still necessary is that the child must differentiate and integrate the primordial sharing situation—himself, from objects of reference, from his means of symbolic communication, from his communicants (others)—so that his symbols represent his objects of reference in a communicative fashion to both others and himself.

Weiner and Kaplan (1963) present the following sequence in the ontogenesis of reference. The first sign that the child is referring himself to a thing and/or indicating it to another is *reaching* (not grasping) outward. This is a concrete action (and possibly affective) indicator that there is a thing which is distant from the child's body toward which he is reaching. At the same time, the child begins to use *call-sounds* that accompany straining movements of his body toward things beyond his reach. These call sounds are the first manifestations of vocal demonstratives. The next step takes place when the child begins *touching* things at a distance from himself in order to indicate it to himself or others. The third step, that of *turning for*

looking or turning toward things in order to refer to or indicate them, leads quickly into *pointing*. This becomes the human's specialized motor-gestural symbolic form of reference. During this same period the child begins to use specific forms of *vocal denotation* such as "da." These vocal denotatives are used both independently and in concert with pointing. Finally, the child begins to use truly *verbal demonstratives* such as "this" and "that." Again, verbal demonstratives are used together with and separately from pointing.

Two theoretical points are made about the developmental sequence of motor/pragmatic or practical means of reference. First, the sequence follows the orthogenetic principle of progressive differentiation and articulation of global action patterns. The gross bodily movements used in reaching become progressively refined and articulate in form from a gross bodily movement to one in which the outstretched forefinger assumes the configuration of a pointer. Second, the sequence follows the organismic principle governing means-ends or form-function relations. At first the function of reference is tied syncretically to forms like reaching and touching, that primarily serve other functions. Eventually a specialized form (means), that of pointing, is shaped out of the percussory forms as if it were a tool designed specifically to serve the reference function (end).

Primitive symbolic forms of depicting referents are first constructed in the bodily and vocal medium and are presentational cognitions. Even a presentational symbol

has a kind of transparency, an inner life shines through its very existence and facticity. The formation effected in language, art, and myth starts from this original phenomenon of expression, indeed, both art and myth remain so close to it that one might be tempted to restrict them wholly to this sphere. High as myth and art may rise, they remain on the soil of primary, "primitive" expressive experiences. Language, it is true, discloses the new turn, the transition to a new dimension, more clearly than the other two, we cannot doubt its connection with the world of expression. There is always a certain expressive value, a certain "physiognomic" character in words, even in those of highly developed language (Cassirer, 1957, p. 449).

The ontogenetic foundations of the representational function are those motor-gestural expressions that are marked by material similarity and spatiotemporal proximity between the symbolic and referential forms. These presentational symbols are the precursors of the linguistic and mathematical symbols that eventually develop. Material similarity and spatiotemporal proximity are first clearly apparent in the baby's motoric and vocal reactions or *co-actions*. For example, 5-month-old babies who get pleasure out of seeing a person in front of them rocking are capable of doing the same in order to make the interesting spectacle last. Co-action is a transitory expressive form toward true *imitative depiction* which

comes into play only when the expression and the presented content are to some extent differentiated—on two different dimensions as it were. In the early movements of the child, there is an affective-sensory-motor unity: expressive movement does not "refer" to or represent the affective content but rather includes this content in the reactive pattern (Werner and Kaplan, 1963, p. 85).

At root, true imitative gestures are still presentational symbols even when some material difference is introduced. For example, a child may imitate the flickering of a light by fluttering his eyelids. Or he may imitate vocally the heard characteristics of objects or his own action. An example of depiction by such naturalistic onomatopoeic expressions used by a child 17 months old is *f-f-f* to designate a match stick because that is the sound of blowing when putting it out (Werner and Kaplan, 1963). This still involves a realistic pattern that presents the content the child is referring to. This is even true of anticipatory gestures such as making sucking and biting movements or sounds such as *num-num* in order to indicate the desire for liquid or food. Now there is a distinct increase in material differentiation and spatiotemporal distancing between the symbols and their referents. Yet they are still primarily pragmatic, presentational symbols.

The transition between presentational and truly representational vocal gestures takes place when the vocal patterns *analogically depict* referents that do not have any sound

properties. Here there is greater material differentiation between the symbols and their referents than in onomatopoesis. Werner and Kaplan (1963) cite many examples, including an 18-month-old boy who called all round, rolling objects such as balls, coins, and rings *golloh*. Werner and Kaplan call these symbolic forms physiognomic and suggest that they are the genetic basis for sound or phonetic symbolism. Werner and Kaplan analyze four transitional forms between the natural depictive forms (onomatopoeic and physiognomic) and conventional forms of designation.

1 Assimilation of an onomatopoeic expression to the conventional linguistic code, for example, one French child went from using *bum* as an onomatopoeic expression for the noise of things dropped to the verb *bumer* to designate "to fall."

2 Composite forms in which a part is an infantile idiomatic expression and a part is conventional, for example, an 18-month-old boy called hammering *poch* which he transformed into *pochmaker* in order to designate workman.

3 Combinatory forms composed of both an idiomatic and a conventional name, such as *bah-sheep* and *shu-shu train*.

4 The child responds with his own idiomatic expression when asked to repeat a conventional word, such as *tah* for spoon and *peep-peep* for chicken.

Things-of-Action The objects of cognition constructed by primitive mental activity do not have contemplative or abstract quality. For this reason they are not considered to be intuitive or conceptual constructs of mental operations but things-of-action. Thus Werner argues that the mental life of the very young child "can be understood only through the assumption that the motor-emotional and sensory factors are blended into one another." His mental constructs are things-of-action.

If it is admitted that the things of the child world are created as much by his motor-affective activity as by objective stimuli, it becomes intelligible, for instance, why a child can seriously consider a few wisps of straw to be a doll or a bit of wood to be a horse (Werner, 1948, p. 65).

This hypothesis also fits some of the primitive behavior of brain-damaged patients. Werner notes, for example, that such patients cannot recognize a key in the abstract but may immediately recognize and name it when it is inserted and turned in a lock, that is, when it becomes a thing-of-action.

It is possible, following Werner, to distinguish for analytic purposes the products (constructs) of undifferentiated mental acts into "things-of-action" when referring to their object character and into "signal-things" when referring to their expressive and communicative character. Thus, boxes and chairs are different kinds of "signal-things" for dogs. Sarris (cited in Werner, 1948) performed the following experiment. A dog was trained to jump on a chair and sit on it at the command "Chau!" and to go and lie down in a basket at the command "Basket!" When the dog was presented with a box that was open at the top, he lay down in it when commanded "Basket." Anything that he could get into and lie down in had the "signal-quality" of basket. He did not respond to the command "Basket" when that same box was covered with a lid. At that point he only responded to the command "Chau" by jumping up and sitting on it. The signal-qualities for the dog were obviously guided by the actions he could perform on it.

Things-of-action are diffusely organized, they are not well articulated as discrete parts of the total environment, and they are rigidly dependent upon the whole constellation of the concrete, sensorimotor, and affective field. Werner cites, for example, the behavior of the spider (*Tegeneria domestica*) waiting for prey. Its behavior is rigid—it will only attack a fly caught in the outer meshes of the web—and diffuse—it will attack any object that vibrates, such as a tuning fork, even if it is not food, and not attack appropriate prey like a fly if it is stationary. This diffuse and inflexible character of sensorimotor products means that they are not articulated as objects that have essential and variable characteristics. They lack the permanence which is prerequisite for a stable, conceptual construction of the field.

A necessary prerequisite for the constant object is an articulation of the concrete field.

to the end that constant elements making up the object will be experienced in sharp contradistinction to the variable elements (Werner, 1948, p 108)

The frog may starve to death if his prey is in front of him but static, when he has been conditioned to react to a particular motion. Such rigidity of behavior could not happen beyond the earliest period of the child's development. The reason for this is that in human ontogenesis things begin to be flexibly articulated at around 9 months of age. Consequently, they acquire a permanent "objective" form which is preserved across transformations of nonessential characteristics.

Permanence is only possible where things are abstracted out of their momentary, concrete action context and embedded in a minimal representational network. This network must include some construction of a stable spatial sense.

The "permanence" of the thing is bound up with the stability of spatial unities. We judge that a thing is precisely this one and continues to be so, chiefly by designating its place in intuitive space as a whole (Cassirer, 1957, p 142).

According to Werner, the most primitive sense of space is "syncretically bound" to the practical activity of the subject. It is therefore a subjective construction that is "physiognomic-dynamic" and "rooted in the concrete and substantial"—it is a "space-of-action." In human ontogenesis space is first known through bodily action, particularly the mouth's sucking on the things with which it comes into contact. It is therefore a transient space of immediate action. Growing out of this, in a few weeks, is "a space-of-nearness, of propinquity, in which the space surrounding the body becomes differentiated from the body proper" (Werner, 1948, p 173). The infant's space becomes bounded by that which he can reach, touch, and see. The limits expand in distance as the infant's visual capacities increase but space still remains a space-of-relative nearness as long as he cannot locomote on his own power. In this sense, the knowledge of space remains a strictly presentational cognition. And his knowledge

of objectification of things in general remains that of a strictly presentational and pragmatic permanence.

Transitional Acts

The mental acts and products that are transitional between precursory and advanced mental life involve many of the features that are characteristic of both. They stand midway between, and are functionally analogous to and partially isomorphic with both concrete presentational and abstract representational phenomena. First of all, they have vestigial presentational characteristics, transitional mental activity being diffusely organized. In ontogenesis this is especially evident when we examine the child's drawing and melodic activities, whether they are spontaneous or copies. Their parallel diffuse organization is summarized in Table 2, as outlined by Werner (1948, pp 122, 127-128).

Diffuse perceptual intuitions are characterized by three central features (Werner, 1948, pp 128-135). The first is a sensitivity to transformations in the external environment and a corresponding lack of identity and conservation judgments. For example, the child may not recognize his parents if they are wearing new clothes. Corroborating evidence on intuitive identity judgments comes from a study calling for verbal judgments (Sigel, Saltz, and Roskind, 1967). Only 42% of 5- and 6-year-olds' responses are positive to questions such as "This father studied and became a doctor. Is he still a father?" Even at the ages of 7 and 8 not all the responses (only 71%) are positive. The second characteristic is lability. Often, for example, the young child changes the meaning of what he is drawing, what he is building with blocks, and even what the words he is using mean as his activity proceeds (Werner and Kaplan, 1952). Indeed, he does not intentionally begin to plan his activity in advance until he is about 4 or 5 years old. The third feature of perceptual intuitions is rigid conservatism or traditionalism. The young child, for example, is likely to insist that the parts of a game be repetitively repeated in a strict order.

Physiognomization is still at the heart of much of perceptual intuition, such as when one young child said "Poor, tired cup" upon observing a cup lying on its side (Werner,

Table 2 Parallels in Primitive Perceptual-Motor Activity

Graphic Activity	Tonal Activity
A tendency toward homogeneity and greater diffuseness may be revealed	
1 In the strong emphasis on qualities of-the-whole	1 Expression of the "quality of the-whole"
a Making a figure more uniform, indivisible $\square \rightarrow \bigcirc$	a Continuity The "glissando" characteristic in the singing of very young infants tends to disappear with older children, but a marked inclination to increase the continuity of the original pattern remains in the event of large tonal intervals ("leveling tendency")
b Closing an open figure $\bigcirc \rightarrow \bigcirc$	b Tonal closure The tendency to a closure of the "open figures" in the drawings is translated here into a tendency to finish with a low note, as the note <i>par excellence</i> , rather than with the actual middle note
2 In the homogenization of directions and parts by	2 Homogeneity of direction and parts
a Making parts alike $\square \rightarrow \square$	a Parts are made more alike (see as examples above the two copies of Motif II)
b Simplifying directions $\ast \rightarrow \nearrow$	b Simplification of direction If the melodic movement is strongly articulated like this (J J J) it will tend toward simplification into this (J J J)
c Using Symmetry: $S \rightarrow C$	c "Symmetrization" of ascending and descending parts frequently occurs whenever the model is asymmetrical
	(J J J) becomes (J J J)
	(Aside from these deviations on a purely melodic basis obvious changes occur which follow a tendency to simplify the harmonic relationship)

W-190 Insert on 51A

1948) Such physiognomization retains the relatively immediate, direct quality of presentational experience when compared with mediated, as-if constructions, such as in acts of personification

Nature when known physiognomically is alive throughout, not because the soul, the vitality, is invested in the inanimate object, but rather because everything is understood to behave dynamically, quite apart from and prior to the differentiation between object and subject (Weiner, 1948, p. 80)

Just as perceptual intuition is infused with affect during this transitional phase, so emotional experience is still relatively fused syncretically with somatic and perceptual-motor activity. Weiner cites, as an example, the exclamation of a 4-year-old girl when given new clothes "The beautiful clothes I'm happy right in the bottom of my stomach!" And at a later age "Oh, you're so wide when

you're happy!" Another important feature of the syncresis of the perceptual and the affective aspects of transitional mental activity is the fusion of ethical with esthetic judgments. Wiener notes that it is not unusual for young children to identify "ugly" with "unjust" and "beautiful" with "good." Even adults often engage in the kind of borderline mental activity where they syncretically fuse "white" with "good" qualities and "black" with "bad" qualities.

The other side to perceptual intuitions is that they begin to exhibit precursory aspects of the abstract, representational features of the contemplative acts that fully develop during the next stage. For example

In the construction of every spatial intuition, of every apprehension of spatial forms, of every judgment as to the position, magnitude, distance of objects, the individual experiences "weave themselves into the whole." In order to be spatially determined in relation

to the whole, every spatial content must be referred to and interpreted according to certain typical spatial configurations. These interpretations, as effected in the sign language of sense perception, may be regarded as primary achievements of the concept (Cassner, 1957, p. 286).

The general hypothesis is that intuitive interpretations and representations begin to

articulate the individual and particular into a determinate totality, and in the particular they see a representation of this totality itself. As intuitive knowledge progresses along this path, each of its particular contents gains greater power to represent the totality of the others and to make it indirectly "visible." If we take this representation as a characteristic determinant of the function of the concept as such, there can be no doubt that the worlds of perception and spatio-temporal intuition can nowhere dispense with this function (Cassner, 1957, p. 286).

The appearance of even rudimentary abstract features is dependent upon increasing subject-object differentiation and the initial development of perspectivism. The child begins to recognize that people may perceive the same event in different ways. He also begins to be able to look at the same event from different perspectives and adopt the point of view of others. However, he will not be able to integrate fully these different perspectives into a coherent world view or ideology until he reaches the truly abstract representational stage.

Progressive subject-object differentiation leads to intuition becoming more circuitous, less immediate mediational means (instruments and devices) are developed for achieving ends. At first this is seen in ontogenesis when children use parts of their body as instruments to deal with and master situations. Lewin's film of a 3-year-old child climbing on a stone and only then turning around in order to sit down demonstrates that even a simple, circuitous perceptual-motor act does not develop until well into childhood. The "increasing specificity of the subjective factor," as compared to objective factors in the determination of conduct, marks the "emergence of a specifically personal motivation"

that is "revealed in the growing intention and complexity of purely personal motives" (Werner, 1948, pp. 191, 194). Werner cites the following kind of evidence: A 2½-year-old child will have no difficulty performing a task (removing every second object in a series) if it has valence for him (each second object is a piece of candy). He will have difficulty with the same task if it has no valence for him (pasteboard combs). As the child begins to recognize that objectivity is dependent upon his own conduct he develops playful behavior. Illustrative of the child's growing capacity to anticipate the end effect of his action is his naming of what he is drawing (see Table 3, from Werner, 1948, p. 198).

Protosymbols. Human mentality reaches the level of abstract concepts through representation—through language and the naming process. However, abstract conceptual representation has its basis in the more primitive symbolic forms of stages "where language itself is identified with concrete action and where names are fused with objects they denote" (Werner, 1948, p. 254). In primitive symbolization names are material parts of the things they represent (e.g., word magic) and are sometimes conceived of as things themselves (Cassner, 1953). Werner (1948) suggests the following developmental basis of symbolization.

In the physiognomic world the name is not a mere instrument of sound behind which there is meaning. The word, by virtue of its concrete physiognomy, is directly related to the object itself. Or it may even go beyond this because the word, in so far as it shares the physiognomy of the objects, is an integral part of this subject (p. 263).

Table 3. Early Age Levels at Which Objects Are Named in Drawing (After Hetzer)

Age (Years)	Not Named	Named Afterward	Named While Being Drawn	Named Prior to Being Drawn
3	90	10	0	0
4	18	9	37	36
5	0	0	20	80
6	0	0	0	100

Figures refer to percentage of cases

Expressive physiognomic qualities that are intersensory in character may exist in the sounds articulated in the human voice

language itself has a physiognomic quality language is the most flexible and refined instrument for expressing the dynamic-motor aspect of the objective world (p 257)

[Eventually] names are no longer thought of as concrete and physiognomic in nature, as constituent parts of objects proper, they gradually achieve the status of symbols substituting for the objects themselves At the same time the physiognomic quality of words may still remain as the sensuous ground from which the abstract meaning draws its vitality (p 264)

Werner (1948) makes three points about the developmental relations of general concepts and symbols The first is that primitive symbolization is characterized by a multiplicity of particular terms and a scarcity of general terms The second is that it remains an open question whether or not preliterate people possess general ideas even when they are not explicitly expressed in their language Generalization may be implicitly expressed in their language when there is no explicit expression The third is that we may find a multiplicity of particulars and a scarcity of generalities even at advanced levels of mentality

The difference between lower and more advanced societies does not consist of the fact that primitive forms of behavior are absent in the latter, but rather that the more primitive the society the greater the homogeneity and the consequent dominance of primitive behavior As the society advances the stratifications of mental form stand out with increasing clarity (p 271)

The underlying tenet about the emergence and development of mental processes is the principle of spiral development all novel psychological functions are first actualized through the use of forms serving genetically prior functions As applied specifically to the ontogeny of symbolization, this general tenet leads to the specific assumption that the function of linguistic representation emerges from and is rooted in prelinguistic, gestural, and intonational forms of symbolization On the

basis of this assumption, it is possible to order genetically analogous manifestations of the symbolic function in terms of the transformations in the form to function relations which these manifestations undergo during the transitional stage from (1) the initial prelinguistic state of syncretic symbolization where the expressive forms of gesture and intonation serve both the functions of representing some referent and the attitude (orientation, feeling, and conation) toward the referent, toward (2) the linguistic state of discrete symbolization where the representative function achieves the autonomy necessary to the development of a form—a medium of representation such as language—that uniquely serves its ends, such as reference, designation, and predication

As the child begins to construct extended verbal expressions to communicate about events during this intermediate stage, these

messages become increasingly differentiated and articulated, so that distinct aspects of an expression come specifically to represent distinct aspects of a complex state of affairs, such as the intent of the speaker, the different components of the situation, and so on (Werner and Kaplan, 1963, p 31)

There are two major aspects to messages, according to Werner and Kaplan (1963) The first is the "attitudinal mode" of the message, that is, whether the intent is to command, declare, question, and so on The other aspect is what the message signifies, that is, whether the reference is to oneself, another object, a concept, and so on The prelinguistic, gestural, and intonational means of symbolization employed during the initial mental stage permit only some diffuse expression of attitude, such as the desire for contact or demand They do not usually permit differentiated and integrated representation of the "three major components of a situation (self-other-object)"

The child's bodily or vocal symbols that no longer simply express an attitude but also refer to situations are said to be *monoremes* At first, monoremes represent syncretically a fusion of attitude and reference They are more like prelinguistic expressions, such as call-sounds that point to desiderata Monoremic expression should be easiest to determine when the child's symbolic orientation is

declarative, for example, when a child points at something and says *da* (there). Even then, however, the declarative aspect of the symbol is at best hypothetical and implicit.

The duration of the monoremic stage lasts from about six months to a year. According to Werner and Kaplan (1963, pp. 136–137), it is marked by two notable developments, an “increase in the *variety* of vocal forms” produced by the child in order to articulate the communicative, referential, and depictive moments of the speech situation, and a progressive differentiation of the nature of monoremes. The intonational variations in the child’s monoremic symbols express “some degree of differentiation among attitudes but not differentiation between important elements of the situation, such as direction towards addressee and object of discourse.” Toward the end of the monoremic stage,

the child produces monoremes in which such aspects of the situation as orientation toward an addressee and reference to an object of discourse are differentiated respectively by intonation and gesture, on one hand, and by the form of the vocable, on the other. exact citation

This movement reflects one of the major laws of development, the genetic principle of *shift of function*. The child is using his well-established expressive forms of “intonation and gesture for novel functions” such as indicating his attitude, and his vocal forms progressively become speech units or “names” that represent objects of reference.

It is not until the child reaches the two-vocable or *duoremic* stage that we may be sure that the child’s intent is explicitly declarative. Now, the function of his verbal forms shifts from “names” to “words.”

A name becomes a word only insofar as it fulfills a grammatical and syntactic function in an utterance, a function beyond its role as designator of something (Werner and Kaplan, 1963, p. 138).

Words, unlike names, are always parts of sentences. Words and sentences co-emerge in development. When vocables become words, then their referents become increasingly delimited. Werner and Kaplan cite an example

from one of Giegoue’s children. When the child was at the monoremic stage he used *bum* to refer to all events in which a loud, abrupt sound played a significant part. Later the child used *bum* or *popot* (porte, door) as holophrastic names to refer to door-closing or door-being-closed. When the child advanced to the two-vocable stage he produced *bum-popot*, such that he delimited banging sound as the distinctive referent of *bum* and door as the referent of *popot*. These distinctively delimited representational relationships “become fixed and stabilized as the child uses them as pivot forms, as in *bum-sonnette* and *ouvrez-porte*.”

A second, related aspect of the progressive differentiation of reference at the two-vocable stage is specification or “the ontogenetic change from vocables having a vague, over-inclusive referent to vocables having a definite more clearly specified referent” (Werner and Kaplan, 1963, p. 142). The most significant function of specification “for linguistic articulation of noun-verb relationships” is categorization of represented events, particularly into things and actions. Werner and Kaplan cite an example from Leopold. At 17 months a child used *auto* to represent the object in motion. At 19 months she began to use action terms (such as *choo-choo* to refer to motion) in combination with thing terms (such as *tram* and *auto*) to produce two-vocable phrases (such as *choo-choo-tram* and *choo-choo-auto*).

The categorical function of specification is “correlative with the integrative trend toward the structuring of sentences.” At the beginning of the two-vocable or duoremic stage “*integration* is very concretely assured through the referential *overlap* of the two vocables.” Werner and Kaplan cite the example of a child who says *da-digda*, where *da* refers to “there” and *digda* to “clock” and both refer to the totality of the sounding clock. The first form of integration then reflects overlapping or holophrastic reference.

Integration is also assured by the external, vehicular aspect of symbols. Werner and Kaplan hypothesize that one major means that the child uses to achieve sentence integration is intonation. During the monoremic stage intonation serves to designate the child’s attitude, orientation, and emotion. During the duoremic stage its function changes to en-

suing initial integration of words. Weiner and Kaplan suggest two developmental steps in intonational integration. The first is even or monotonous stress where the child produces both vocables with the same intonation. The second step occurs when the child uses uneven stress so that the intensity, pitch, or duration of the intonation is different for the two words. The use of intonation as a means of representation reflects two major developmental principles: (1) the genetic principle of *shift of function*, here, the shift in the function of intonation from designation to sentence integration, and (2) the genetic principle of spiral development, here, "the temporary return to more primitive means of representation, such as intonation, when realizing more complex acts of mentation" (Weiner and Kaplan, 1963, p. 132).

A major function of speech, particularly in its sentence form, is the construction and expression of predicative judgments or assertions. The earliest ontogenetic predications are judgments of identification.

In explicit verbal manifestation, these judgments take the form "this (pointing) is a B" or "A is a B." The earliest forms of identifying predications occur in situations in which the child "names" a presented content (Werner and Kaplan, 1963, p. 160).

Eventually, in later stages of development when the child has well developed his capacities for conventional sentential designation, "identifying predications subserve class inclusion and exclusion: one asserts that 'A is a B' or 'A is not a B'" (Werner and Kaplan, 1963, p. 162). Before the child can produce judgments and predications of actions (by an agent) and of attribution (of a quality to a thing) he must be able "to distinguish between thing and some state of thing within a global, concrete happening." Then he must distinguish between states of action ("doing") and attribution ("belonging to").

Weiner and Kaplan outline four sequential steps in the formation of predication or symbolic judgment.

(1) The earliest pre-predicative utterances are, both referentially and linguistically, of an undifferentiated character, that is, they are monoremic. (2) Next come two-vocable

utterances which are initially a junction of monoremes, in which each denotes the same event, while connoting somewhat different aspects of it. —a loose joining of relatively separate vocables. (3) At a later stage of the two-vocable utterances, the units become relatively distinct in reference and are eventually linked together in an intonational hypotaxis (uneven stress)—indicating that one referent is in some way dependent upon the other. (4) Finally, specific morphological means, such as form-words, come into play to establish integration of the vocables entirely within the linguistic medium per se, at this point "sentences" are fully established and, correlatively, so are "words" (1963, pp. 168-169).

The final major function that speech begins to serve in this intermediate stage is the formation and expression of "*relations between thoughts*." Werner and Kaplan hypothesize two ontogenetic phases.

whereas the structures of the earlier utterances, depictive of the order of pragmatic-perceptual happenings, are closely tied to, and interwoven with, concrete contexts, later utterances are increasingly freed from contextual embeddedness, this decontextualization of speech goes hand in hand with a stress on conceptual-logical rather than pragmatic-perceptual relationships among experiences (thought) (1963, p. 182).

The authors document this hypothesis with many examples of the developing expression of coordinate, sequential, simultaneous, antithetical, subordinative and causal relations in child language. The idea is that at first the child's utterance closely reflects his observation so that he may say something like "The toy is broken—it doesn't move." Then the child begins to conceive of concrete causal relations, he observes an effect which leads him to anticipate and look for the cause so that the child may say something like "It doesn't move because it's broken." Eventually, at the next stage the child abstracts the logic of this class of events and may say something like "Because it is broken, it doesn't move" where the particularity of the figural event is expressed in relation to a logical ground about the class of causal events.

Perceptual Intuitions. During this stage, percepts retain four major characteristics of primitive mental activity. The first is physiognomization. In a series of experiments with children ages 6 to 19, Wapner and Werner (1957) examined the effects of "directional dynamics" in pictured objects and visually presented words upon perception. One experiment, for example, compared the perceived speed of motion of (1) objects that have a static quality (e.g., a "sitting mouse") or objects that are pointed in the direction opposite of the movement (e.g., a series of triangles like  moving left to right) with (2) objects that have a dynamic quality (e.g., a "running mouse") or objects that are pointed in the direction of the movement (e.g., the same series of triangles but whose apexes now faced in the same direction as the motion). The effects of the directional dynamics was greatest for the youngest subjects and decreased with age. Their studies lead the authors to conclude

these developmental trends have been related by us to the developmental principle of increasing object-subject differentiatedness. Developmental theory assumes that dynamic perception entails relative unity (undifferentiatedness) between object and organism. Since this undifferentiatedness decreases with age, the potency of the dynamics inherent in objects decreases with increase in age (Wapner and Werner, 1957, p. 36).

The second characteristic is psychophysical undifferentiatedness. For example, a child who perceives a few pieces of straw as a doll may have no awareness that he is attributing these doll-like qualities to the straw. Rather, his percept may be the result of a lack of differentiation in his total psychological organization between his subjective (motor-affective-perceptual) state and the objective matter-of-fact attributes of things (e.g., Werner and Wapner, 1955; Langer, Wapner, and Werner, 1961; Langer, Werner, and Wapner, 1965).

The third primitive characteristic of intuitions is syncretism of percepts and images, for example, in eidetic imagery, which was first described in detail by Jaensch (1930). These images have much of the force, the "sensuous vivacity," and detail possessed by percepts.

Consequently, some children feel that their images are "real projections on some surface in outer space involving no effort of will" (Werner, 1948, p. 143). In this sense, eidetic imagery is tied to sensory phenomena. On the other hand, it also partakes of qualities characteristic of imaginal phenomena. Unlike sensory after-images, eidetic imagery can be influenced and intentionally altered by the creative will of the child. Eidetic imagery, like children's drawings, is particularly susceptible to what Werner calls the "emotional perspective." Jaensch reports, for example, the case of a boy who was so impressed by a play that the actors grew to enormous proportions before his eyes.

The fourth primitive characteristic of intuitive perception is its lack of stability. In their sensoritonic theory, Wapner and Werner (1957) posit that the underlying mechanism of perception is an equilibration process between sensoritonic forces within the organism. The theory makes the holistic assumption that sensory and tonic (postural-muscular) forces "must be essentially of the same nature," even though they may appear to be different sources of perception, because they have parallel effects and they influence each other. The organism is in a relatively stable state when his interactions with the environment result in sensory and tonic states that are in equilibrium with each other. Unstable states are the result of interactions that result in sensory forces that perturb the tonic forces, or vice versa. Such an unstable state may be examined experimentally by tilting an individual in a dark room and testing its effect upon his perception of major spatial coordinates, such as the vertical represented by a luminescent rod. The hypothesis is that at primitive stages in the development of perceptual intuition the organism does not have stabilizing forces to counteract the perturbing forces in the direction of the tilt (cf. Goldstein, 1939). Consequently, the rod will appear to be vertical when it is actually tilted in the same direction as the organism. At advanced stages of perceptual intuition, on the other hand, the organism develops stabilizing counterforces in the direction opposite to those induced by the tilt in order to reestablish equilibrium. This often involves counteractive forces that overcompensate for the perturbation. Consequently, the resultant perception may not be

"veridical." For example, the rod may be perceived as vertical when it is actually tilted in the direction opposite the tilt of the organism. The comparative data conform to this sensoritonic hypothesis

1 Children 6 to 16 and older people 65 to 80 locate the apparent vertical to the same side as their own tilt (Comalli, Wapner, and Weiner, 1959)

2 Catatonic-hebephrenic schizophrenic adults locate the apparent vertical to the side of their own tilt (Cairns, 1955)

3 Normals, 16 to 50 years old, locate the apparent vertical opposite the side of their own tilt (Comalli, Wapner, and Weiner, 1959)

The intuitive perceptual sense that develops also becomes progressively detached from the subject and objectified as a separate but still concretely understood external world. As a paradigmatic example of the progress achieved let us consider the intuition of space that develops beyond the immediately perceptible. Its most primitive manifestation is usually supported by the physiological maturation of locomotor powers that permit wider exploration and memory that permits the temporal extension of space into familiar but not presently experienced places. In this sense, spatial cognition begins to be representational. But, for these very same reasons, spatial knowledge is still very much tied to the particular activity of the subject, it is, in Werner's terms, a "personal space-of-action" and not a general concept. An example from human ontogenesis is that 3-year-olds are likely to be disoriented if they are taken into a familiar place by an entrance that they have previously used only as an exit.

The most advanced manifestation of the concrete intuition of space is one in which regions are differentiated and systematized into a whole organization. But it is still a personalized organization that is intrinsically interwoven with the idiosyncratic and physiognomic activity of the acting subject. This stage is central to ethnogenetic comparisons because much of the mythical organization of space seems to involve reasoning that does not go beyond the concrete intuitive level. This seems to be as true of the astrological, cosmic spatial concepts that are becoming increasingly prevalent in contemporary cul-

ture in the United States as it is, for example, in the religious partitioning of space in Zuni or early Babylonian ideologies (Cassirer, 1955)

[Highly organized mythical space] retains some of the salient properties of primitive space, particularly its concreteness and dynamism. This qualitative dynamism may come to view in such physiognomic or expressive terms as "holy" or "unholy," qualities on which a mythical space may be based (Werner, 1948, p. 171)

Myth arrives at spatial determinations and differentiations only by lending a peculiar mythical accent to each "region" in space, to the "here" and "there," the rising and setting of the sun, the "above" and "below." Space is now divided into definitive zones and directions, but each of these has not only a purely intuitive meaning but also an expressive character of its own. Space is not yet a homogeneous whole, within which the particular determinations are equivalent and interchangeable. The near and far, the high and low, the right and left—all have their uniqueness, their special mode of magical significance. Not only is the basic opposition of sacred and profane interwoven with all these spatial oppositions, it actually constitutes and produces them. One must immerse oneself in the artistic representations of the gods and demons of the directions—as we find them for example in the ancient Mexican culture—in order wholly to feel this expressive meaning, this physiognomic character which all spatial determinations possess for the mythical consciousness. Even the systematic order of space (for this is by no means lacking in mythical thinking) does not go beyond this sphere. The augur who marks off a templum, a sacred precinct in which he differentiates various zones, thus creates the basic precondition, the first beginning and impulse toward "contemplation." He divides the universe according to a definite point of view—he sets up a spiritual frame of reference, toward which all being and all change are oriented. This orientation is designed to insure a vision of the world as a whole, and with it a prevision of the future. But of course this vision does not move within a free, ideal, linear structure, as in the realm of pure "theory",

the zones of space are inhabited by real, fateful powers, powers of blessing or of doom. The magical circle that embraces the whole existence of nature and of man is not burst asunder but only reinforced, the distances conquered by mythical intuition do not break its power but serve only to confirm it anew (Cassirer, 1957, pp. 150-151).

As for ontogenesis we find that although the child is beginning to differentiate locations, the way in which he relates them into a spatial organization is still egocentrically bound to his own action at the beginning of this stage rather than in a perspective fashion. For example, by the age of 6 or 7 years, children know what right and left is on their own body. But they cannot tell right from left on other bodies, and they mirror image the movements of another person when required to imitate. Toward the end of this stage, the construction of spatial coordinates begin to be detached from the actions of the subject. Children begin to discriminate right from left on other bodies as well as their own. But even at 8 years they can still hardly imitate correctly someone facing them who moves his right and left hands (Wapner and Cuiilo, 1968).

Werner cites further comparative evidence from pathogenesis. For example, Head (1926) reports that aphasiac patients place their right hand to their right eye when imitating Head's placement of his left hand to his left eye. The imitation, then, is mirror-like. Another aphasiac patient was only able to distinguish right from left in terms of his own activity—right is the side with which he writes. These kinds of observations led Werner (1948) to the hypothesis that mental disturbances are often marked by conceptual regression to relatively primitive notions of space: spatial cognition becomes egocentric, affectively laden, physiognomic, or dynamic—a concrete "space-of-action."

Werner's (1948) central hypothesis is that the perceptual intuition of space is rooted in "the property of a temporal succession, that is, irreversibility." As an example he cites the Scupins's report of their son Bubi's behavior when he was 7 years old:

Today Bubi was taken through the woods by the forester. Without following any path,

over brooks, mounds and through clearings he went to the tree-nursery where the men were digging. On the way back, at a spot some five-minutes' walk from the forester's lodge, the man showed the boy a strawberry patch. In the afternoon the child's mother, armed with a pail, thought she would let him lead her to the strawberries. Unable to reconstruct the return route in a reversed direction, the boy led her all the way through the woods, over the brooks and through cleared spots to the place where the men were at work at the nursery, and thus found his circuitous way to the strawberry patch. To her amused astonishment, Bubi's mother found that it had taken her three-quarters of an hour of trail-making to arrive at a place not five minutes' distance from the forester's house where they had started. A whole chain of associations and memories had guided him. He spoke in a long monologue, saying "Here at the threshold the forester said, Watch out! Here's a step up! Here the forester said, Sit down and slide. Here—wait a minute—how do you go from here? Oh, yes—the grass is trampled—we're right. There's Gold Brook already! The forester jumped across first and reached over his stick to us. Look! there are the men working!" (pp. 176-177).

Contemplative Acts

Abstract conceptual activity requires that from the totality of experience "a factor is not only detached by abstraction but at the same time taken as a representative of the whole" (Cassirer, 1957, p. 114). This means that symbols are created that not only stand for and are integrated with—but are fully detached and differentiated from—what they represent. This permits the articulation (differentiation and integration) of experience from many perspectives, not only one's immediate involvement. Symbolic representation is therefore necessary to the construction of ideological consciousness or theoretical cognition in which subjective perspectives are finally related in a logical fashion with objective perspectives.

Abstract contemplation, then, is based upon schematization that is intentional and planned (Werner, 1948, Werner and Kaplan, 1963). The detachment from immediate and pragmatic involvement permits contemplative schematization to go beyond presentational

construction of here and now experience to an interpretative representation of past experience and future possibilities as well as of present activities. Observed transformations over time are no longer accepted in their presentational guise but are represented in relation to reversible mental interpretations. This means mental coordination of the observed present actual transformation with the nonpresent possible reversibility of that deformation. Intentional schematizing is also stable and flexible. Intentional schemes are constructs in which interpretations become principled in their meaning so that they do not simply fluctuate due to context. Yet they are plastic enough to permit for modification where the conditions indicate qualification. They have, then, the character of principles that have universal definition and particular qualification.

Thus schematization reaches its highest form during this stage when two criteria are met. The first is the development of the categorical and hypothetical "attitude toward the possible" (Goldstein, 1939). The most advanced manifestation of the *categorical attitude* is the ability to deal with possibilities as well as with actualities in a principled fashion.

Previously we mentioned a certain detachment from experienced situations as prerequisite to the adoption of the "categorical" attitude. Such detachment permits the normal person not merely to experience the actual situation and to undergo the effectiveness of operating factors, but also to explicate the given situation, to apprehend and thematize effective factors, and, eventually, to orient his actions with respect to factors thus rendered explicit (Gurwitsch, 1949, p. 183).

The second criterion is the development of the *transcendent capacity* to act mentally upon one's own psychological actions, thereby permitting the organism to contemplate its own thoughts and be conscious of its consciousness. Both these developments are prerequisite to the formation of theoretical, perspectivistic, and ideological cognition of physical, social, and psychological experience.

In theoretical cognition the "schematism of images has given way to the symbolism of principles" (Cassirer, 1957, p. 467). This permits the formation of logical systems of action

that create abstract or formal ordering relations. Thus the final character of mentation as representation emerges: abstract symbolism that permits the construction of principled concepts which are logically necessary, and have general meaning yet maintain their particular intuitive reference.

The meaning of a principle must ultimately be fulfilled empirically, hence intuitively, but this fulfillment is never possible directly, it can only occur when other propositions are derived by a hypothetical deduction from the assumption of the principle's validity. None of these propositions, none of these particular stages in a logical process, need be susceptible of direct intuitive interpretation. Only as a logical totality can the series of inferences be related to intuition, and confirmed and justified by intuition.

It is the construction of a network of logical principles, such as the principle of invariant relations in the concept of the conservation of energy, rather than the positing of the existence of particular things which characterizes the most advanced form of objective schemata.

Here the substantial is completely transposed into the functional: true and definitive permanence is no longer imputed to an existence propagated in space and time but rather to those magnitudes and relations between magnitudes which provide the universal constants for all description of physical process (Cassirer, 1957, p. 473).

The mental representatives of these functions are symbolic relational schemes, such as the operation of reversibility, that have the objective force of logical necessity.

Symbols. The progressive development of autonomous symbolization is marked by the construction—the appreciation and understanding, as well as the production—of symbolic forms that are progressively differentiated from the referents they represent. With respect to the linguistic medium this

increasing *distance* and independence of language from the domain of concrete, perceptual-motor experiences reflects itself in several ways: increasing reference to phenom-

ena remote from concrete perception, formation of names to refer to class concepts rather than to individual concepts, formation of designators of abstract rather than context-bound relations, etc (Werner and Kaplan, 1963, p 184)

The concept of distancing leads to the derivative idea that "the use of purely linguistic operations for constructing referents and relations among referents" is a major function of symbolization. This takes many forms in the course of ontogenesis. One form is "composition, the joining of two names to form a new unitary name." Many of the composites formed by children, such as "birthday-tree," are tied to specific spatiotemporal contexts and are of short-term duration, others endure a long time. A related form is "derivation, the adding of form-elements to a name in order to derive new names (and concepts)." This occurs when the child already discriminates between "nouns as thing-words and verbs as action-words" but for the purpose of a novel function, constructing new words, he returns to the use of a more primitive form in which things and actions are not differentiated, e.g., a 5-year-old boy called a towel a "wipe-it-dry."

A more advanced symbolic form of constructing relations between linguistic concepts is that of defining the meaning of words by other words (Lewis, 1929). At first the child's *lexical constructions* are "global, diffuse, and concretely contextualized." When 5- and 6-year-old children are asked what "bottle" means they give answers such as "There's lemonade in it" and "When a little boy drinks milk out of it." Eventually the child's lexical units become "relatively context-free" and general, for example, one child defined a bottle as "A container into which all kinds of liquids go."

When words acquire general, decontextualized meanings, then they truly attain the level of *autonomous lexical units*. Werner and Kaplan (1963) hypothesize six steps in the formation of autonomous symbols. This hypothesis is based upon a study (Werner and Kaplan, 1952) of 8½- to 13½-year-old children. These children were presented with twelve series of six sentences each. The same artificial word appeared in each series of six sentences. For example, the artificial word in

one series was "hudray" (its adequate translation was grow, increase, or expand) and one of the sentences was "If you eat well and sleep well you will *hudray*." The child's task was to find the meaning of "hudray" that would fit all six sentences.

Young subjects tend to ascribe a "global connotative sphere" to the artificial word that reflects what the context means to them. This "word-sentence undifferentiatedness" means that they do not treat the word as an autonomous lexical concept. Not only do these children fuse the meaning of the word with that of its sentence context but they also fuse or intermingle the different structure of the various sentence contexts. For example, even a 10-year-old said that "hudray" means "feel good" in the above sentence, he then translated the second sentence "Mrs. Smith wanted to *hudray* her family" into "Mrs. Smith wanted her family to *feel good*", after which he translated the third sentence "Jane had to *hudray* the cloth so that the dress would fit Mary" into "Jane makes the dress good to fit Mary so that Mary *feels good*", and so on for the rest of the series. Thus the child's syncretic construction leads to a global and diffuse concept in which words and sentences are relatively undifferentiated.

A step beyond this "word-sentence fusion" is partial detachment and partial fusion of the word meaning with the sentence contexts. For example, one 10-year-old assigned the meaning "collect" to the artificial word "lidber" in the sentence "Jimmy *lidbered* stamps from all countries", but then he went on to incorporate "stamps" into the meaning of "lidber" as in "The police did not allow the people to *lidber* on the street," which he translated as "The police did not allow the people to *collect stamps* on the street." Thus both word-sentence and sentence-sentence meanings overlapped.

A third level is achieved when children no longer have trouble assigning meaning to the word in each sentence, but the meaning is context specific. Each time the word appears they give it a new specific significance that fits the particular context rather than arriving at a general meaning that fits all the sentences in the series. The task demand of arriving at a general meaning is often dealt with at this stage by assigning "a meaning comprised of an *aggregation* of the context-specific

meanings. For example, a 10-year-old first translated "contavish" as "cardboard" in the sentence "You can't fill anything with a *contavish*", then as "room" in "The more you take out of a *contavish* the larger it gets", and finally as "cardboard and room" when asked for a general meaning so that he then translated the second sentence into "The more *cardboard* you take out of a *room*, the larger the *room* gets."

At the next stage children assign both a different specific meaning to the artificial words in each context and a general meaning. Then they globally integrate "the specific meanings to the over-all meaning in a vague, subsumption-like relationship." That is, each specific referent is diffusely subsumed under a general class. This pluralization means that the sentence contexts are discretely articulated from each other. For example, one child interpreted the word "prignatus" as meaning "hit back" in "Boys sometimes *prignatus* their parents", then as "lie" in "Mary did not know that Jane used to *prignatus*", then as "holler at" in "Mother said, 'Jimmy you should never *prignatus* your own mother'", and so on. The overall meaning that the child assigned to "prignatus" was "not respect your elders."

The development of the related operation of transposition follows pluralization as a means of trying actively to arrive at an overall meaning while retaining the word's context-specific significance that is also syntactically adequate.

This demand is met by expanding the meaning of one context-specific solution—equating all the other context-specific meanings with that one solution. This "equating" is done by means of such expressions of assimilation as "like-a," "sort-of," "kind-of" (Weiner and Kaplan, 1963, p. 196).

For example, an 11-year-old translated "corplum" as "bar" in "Corplums may be used to close off an open place" and then translated "A *corplum* may be used for support" as "A *leg of table* may be used for support, *bar* fits—a *leg of table* is a *sort-a bar*." Transposition permits the structuring of a discrete sentence context "but the meaning of the circumscribed vocable is not yet of a truly general character." For this reason it does not

yet have the most advanced character of a symbolic concept.

The final development of symbolic concepts described by Werner and Kaplan (1963) involves the formation of general meanings that transcend the specific contexts yet fit each particular manifestation in terms of both its semantic reference and its syntactic requirements. They cite the following response as an example of this principled form of symbolization.

For *prignatus*, one child gave *lie to* as its meaning in the first sentence. Boys sometimes *lie to* their parents, for the second sentence, the solution was *cheat*. Mary did not know that Jane used to *cheat*, *deceive* was the solution for the fourth sentence. You may *deceive* someone but you will not get away with it often. *Deceive* was then used to subsume both *lie to* and *cheat*, it was a word-meaning that could be fitted into all the sentence-contexts without entailing either vague reference or syntactic distortion (Werner and Kaplan, 1963, p. 197).

Concepts. Now the full organizational and functional nature of conceptual schematization becomes manifest. Concepts are the products of mental acts. All conceptual acts evaluate. This evaluation is *logical*; it seeks to come to a principled understanding of empirical actualities and hypothetical possibilities. This evaluation is *intentional*; it is directed toward transcending immediate practical involvement in order to achieve some understanding for the sake of understanding. This evaluation is *esthetic*; it demands continuing rotation of the problems and the solutions until a feeling of equilibrium—fittingness and elegance—is achieved. The resultant conception is not a static achievement but a dynamic process that points to certain judgments. Conceptual judgments are, of course, evaluative acts, which is what initiated the entire process: thus cognition comes full circle. At the same time, they are acts that evaluate in a new light thereby suggesting new considerations, problems, and ideas for consideration: thus cognition develops. Conception

is no ready-made path but a function of pathfinding itself. Intuition follows set

paths of combination, and herein consists its pure form and schematisms. The concept, however, reaches out beyond these paths in the sense that it not only knows them but also points them out, it not only travels a road that is opened and known in advance but also helps to open it (Cassirer, 1957, p. 289).

each newly acquired concept is an attempt, a beginning, a problem, its value lies not in its copying of definite objects, but in its opening up of new logical perspectives, so permitting a new penetration and survey of an entire problem complex. One of its essential tasks is not to let the problems of knowledge come prematurely to rest, but to keep them in a steady flux, by guiding them toward new goals which it must first anticipate hypothetically. Here again we find that the concept is far less abstractive than prospective, it not only fixes what is already known, establishing its general outlines, but also maintains a persistent outlook for new and unknown connections (Cassirer, 1957, p. 306).

We are only now beginning to reveal some of the fundamental characteristics of the most mature forms of conceptual schematization, particularly as it manifests itself in scientific thinking (e.g., Snell, 1953, Kuhn, 1962). The study of sophisticated forms of thinking not only gives us some understanding of advanced conceptual activity but it indicates to us, and reinforces Weir's hypotheses, about the intuitive sensorimotor precursors of full-fledged concepts.

The ability to take into account more than one's own subjective perspective seems to be one fundamental characteristic of sophisticated thought. The product of *perspectivism* is the formation of concepts that are relative to the perspectives they must take into account. This is apparent in the development of spatial ideas that become progressively based upon integration of other perspectives with that of the constructing subject. An ontogenetic illustration is the ability of older children to transpose rather than mirror the movements of others when imitating them. Transposition in imitation indicates "the internalization of the left-right distinction occurring in action and the representational

coordination of perspectives" (Wapner and Cuillo, 1968, p. 887). Thus spatial ideas become progressively detached from the subject's intuitive action and from concrete phenomenal relations. First, they become objectified as separate, concrete external containers with contained objects. Eventually, they become objectified as complex configurations for empirical examination and logical conceptualization.

A second major characteristic of advanced conceptual schematism is its progressive *transparency*. Conceptual transparency means that the mental operations involved are increasingly those of formulating and manipulating sets of hypothetical principles. These principles have their developmental foundation in concrete acts. But they become progressively detached from pragmatic, empirical intuitions. Increasingly they become based upon a hypothetical attitude that is directed toward the intention to know and understand. Principles therefore become progressively founded upon the construction of a logical network of theoretical possibilities. This is clearest in scientific thinking, which constructs hypothetical principles—theoretical fictions or mathematical functions—that are themselves not observable yet are said to represent the essential and universal properties of reality.

What we define as the ultimate physical reality has cast off all appearance of thingness: there is no longer any meaning in speaking of one and the same matter at different times. And yet the abandonment of thingness does not impair the objectivity of physics but grounds it in a new and deeper sense. What we call the object is no longer a schematizable, intuitively realizable "something" in accordance with the definition which Kant worked out clearly in principle, it is a mere X "in relation to which representations have synthetic unity" (Cassirer, 1957, p. 473).

Progressive transparency also means that the symbolic forms involved are increasingly those of constructing and manipulating *stipulated conventions*. These conventions have their developmental foundations in expressive acts and models. But they become progressively distanced from motivated, presentational signifiers and become transparent ve-

hicular media for defining logical relations (Werner and Kaplan, 1963) Cassner (1957) describes the epistemological development in the physical sciences from concrete concepts to principles

a scientific principle, regardless of its particular character, belongs, if only because of its universal logical dimension, to a different sphere of validity—it is fully expressed only in a universal proposition. And every such proposition comprises a specific mode of postulation. Its relation to the world of intuitive phenomena is mediated throughout—that is, it passes through the medium of signification (p. 461)

A final, related characteristic of advanced conceptual schematism is its progressive *heuristic potency*. The categorical concern with the construction of hypothetical possibilities means that conceptualization is now intentionally directed toward the creation of new forms that transcend empirical experience. The intention is to create a psychological reality that has political, ethical, and esthetic as well as physical and logical form. This psychological reality marks the final hierarchical integration of objective and subjective systems in the creation of conceptual forms. Its manifestation in scientific thinking is the formulation of theoretical principles that are logically coherent and esthetically elegant. Its manifestation in personal thinking is the development of ideological cognition that not only makes rational sense but is emotionally satisfying.

CONCLUDING REMARKS

A chapter of length at least equal to the present would have to be written in order to seriously evaluate the success of the comparative organismic perspective. Also, it is obviously too soon to pass any definitive judg-

ment upon the theory as a whole. Yet it seems clear that the approach has already borne fruit in a number of domains. It has been most successful in the study of cognitive phenomena, particularly phenomena of concept and symbol formation. It also has rich potential for the investigation of personality and social development from a genetic epistemological stance, but, to date, this potential remains relatively dormant except for some rudimentary stirrings (e.g., Werner, 1948, Chaps. XII and XIII, Kaplan, 1966a, Witkin, 1962, Langer, 1969, pp. 174–177, 1970, Kohlberg, 1969).

Ultimately, the genetic epistemological aim of comparative organismic theory is to comprehend the totality of mental life and its development. This requires a holistic conception of mental acts since they are the stuff of—construct and generate the development of—mental life. A holistic conception implies that mental acts are feelings as well as judgments. This means that they are both conceptual and motivated acts: the stuff of mental life and development is evaluative conduct.

It should be abundantly apparent by now that Werner's overall aim was to fashion a theoretical perspective that would be applicable to the study of all mental development, whether the primary purpose of the study is empirical, analytical, explanatory, descriptive, etc. This theoretical strategy rests upon the fundamental methodological assumption that all psychological investigations involve (1) a comparison of the invariant and changing features of the same mental phenomenon when it is in two states or (2) a determination of the similarities and differences in comparable mental phenomena. This means that the lawful investigation of psychological phenomena is at root developmental in nature. And it means that a comprehensive account is possible by creating a comparative psychology of mental development.

11. Sensory and Perceptual Development¹

HERBERT L. PICK JR., AND ANNE D. PICK

I NATIVISM-EMPIRICISM IN RELATION TO THE DEVELOPMENT OF SPACE PERCEPTION

Perceptual development, at the intersection of the fields of perception and developmental psychology, has been included in the recent resurge of interest in both these fields. The revitalization of interest in perception no doubt stems partly from the failure of classical learning theory to handle adequately the stimulus input or even to define the effective stimulus. In any case general experimental psychology has achieved a new balance, with perception again sharing a position of prominence. In developmental psychology the disenchantment with the normative-descriptive

approach to the study of children has evolved into a more analytic investigation of the determiners of children's behavior.

A particularly important impetus to the study of perceptual development from the realm of developmental psychology is the work of Piaget. Piaget's view that an early sensorimotor stage is a precursor of intellectual development and his observations of the spatial conceptions of children have inspired interest in children's perception. At the same time, better techniques for measuring sensitivity in young children have been developed. These include use of unconditioned orienting responses (Bartoshuk, 1962a, 1964; Keen, 1964; Engen, Lipsitt, and Kave, 1963), conditioning procedures (Papousek, 1967), studies of stimulus preference (Fantz, 1966; Ames and Selfan, 1965; Heishenson, 1964), and physiological techniques (Eichorn, 1963).

Another general impetus to the study of perceptual development is the importance attributed to early experience and sensory stimulation by Hebb and by the ethologists. Indeed, Hebb's ideas were developed in the context of perceptual problems and the perceptual aspects of discrimination learning. The ethologists' observations on the stimulus specificity in imprinting and the specificity of releaser stimuli called the attention of psychologists to the importance of stimulus determinants of behavior and of the possibility of changes of such determinants with development.

These trends all fell upon the background of a persistent concern of psychologists with the nature-nurture problem of perception—nativism versus empiricism. Hochberg (1962) recently reviewed the history of the contro-

¹ This chapter was prepared while the first author held an NIH Career Development Award 5 KO3 HO 12396 and the second author held an NIH Postdoctoral Fellowship FD HD-32,895. The work was also supported by NIH grant MH 07631 to the University of Minnesota and by the Center for the Study of Human Learning at the University of Minnesota. The reader is also referred to other general review articles on perceptual learning and development by Eleanor Gibson (Gibson and Olum, 1960; Gibson, 1963a, 1963b) and by Wohlwill (1960, 1966). These sources have been especially helpful to the present authors. The authors are especially grateful to Professor Eleanor J. Gibson for allowing us to read the manuscript of her forthcoming book, *Principles of Perceptual Learning and Development* (1969). Our long association with her and with Professor Richard D. Walk, our former teachers, has greatly influenced our ideas and approach to the problems of perceptual development, and we are pleased to acknowledge our indebtedness to them.

versy, pointing out changes in the specific questions, methods of study, and interpretation of results. It is clear from his review that neither the *strong* empiricist nor the *strong* nativist position has been held for a long time. These positions were, respectively, that *all* perception is based on prior experience which fell on an initially blank tablet of a mind, and that all perception is independent of prior experience and reflects the operation of an innate mind. The more typical and weaker positions have tended to emphasize just the role of prior experience, on the one hand, or the role of innate processing mechanisms, on the other. It is also clear from the Hochberg review that until recently few directly studied the development of perception; rather, inferences were made about perceptual development on the basis of introspection or experiments with adults.

Empirical and experimental work on the development of perception began fitfully in the 1930s and gained great momentum in the 1950s and 1960s. As data directly relevant to perceptual development were accumulated, the nature of the nativism-empiricism question changed. In general, investigators no longer were concerned with proving the innate or the acquired character of a specific type of behavior. Rather, they accepted a view of the interaction of heredity and environment in the development of perception and felt that the researchers' task was to define the nature of this relation. This change was perhaps instigated by some of the work on instincts by animal behaviorists (see Lehman, 1953) and by some of the work on the nature of intelligence (see Anastasi, 1958).

Still, some of the problems of perceptual development were set by the long-standing nativism-empiricism controversy and are best understood in relation to these differing theoretical viewpoints. Both views focused on the paradox that our perception is better than it ought to be on the basis of a superficial analysis of the proximal stimulus. This paradox was most vividly exemplified by the phenomenon of depth perception, wherein we see three dimensions although the retinal image is a two-dimensional stimulus. Both the nativists and the empiricists resolved this paradox by enriching the impoverished retinal image. The empiricists invoked the effects of past experience, adding them to the present stimulation

to produce a final resultant percept. The nativists invoked a physiological or pseudophysiological mechanism to modify the effects of the present stimulation. Although both groups addressed themselves to many aspects of perception, in recent years the investigation of depth perception seems to have been most closely associated with empiricists, whereas investigation of form perception has been more closely associated with nativists.

A. Development of Depth Perception

Brunswik has developed the most explicitly empiricist point of view currently concerned with depth perception (Brunswik, 1956; Postman and Tolman, 1959). In this view most of the classical cues of depth perception such as size of retinal image, degree of convergence of eyes, and linear perspective form the basis of depth perception. These cues are utilized according to an individual's past experience with them. The novel aspect of Brunswik's position is his suggestion that the cues are probabilistically weighted by the perceiver in terms of their validity, and this validity is an ecological variable which one can measure. Indeed one of Brunswik's students did measure the ecological validity for depth of such cues as brightness and vertical position in the visual field. A typical example of his data was that the height of objects in the visual field had a correlation of .6 with their distance from the S (Postman and Tolman, 1959, p. 552). Since in this theory accurate depth perception is based on prior experience with differentially valid cues, Brunswik would predict that depth perception should improve with age. Some of his work on the development of the perceptual constancies supports this prediction. Of course, all variations of the empiricist point of view predict improvement of perception with age. In the perception of depth there are obvious ways in which the effects of past experience could function. It is understandable then that empiricist psychologists have addressed themselves to this problem. Before 1960 the studies were confined exclusively to children of preschool age and above, and these will be reviewed presently.

Since 1960 techniques for investigation of sensitivity in neonates and young infants have been developed to the point where it is quite feasible to investigate perception of depth at

this early age. The reader is referred to Chapter □ (by Kessen) for details of these techniques. It suffices to say here that so far procedures involving stimulus preference and operant conditioning have been used to assess infants' ability to perceive depth.

Fantz (1961a) observed durations of eye fixations when infants of 1 to 6 months of age were presented with a disc and sphere of equal diameters. Infants spent significantly more time fixating the sphere. Fixation preferences were tested using binocular and monocular viewing, rough and smooth test stimuli, and direct lighting. The most reliable preference for the sphere was manifest when textured objects were illuminated by direct light. The same preferences were manifest when viewing monocularly or binocularly. If it is assumed that infants fixate the sphere longer because they detect its solidity, this result is surprising, it implies that the pictorial cues of shading and texture operate earlier than the "primary" cue of retinal disparity.

The other stimulus preference method used to investigate infant depth perception employs the visual cliff developed by Walk and Gibson (1961). In this technique the infant is placed on a centerboard between two glass surfaces onto which he can crawl. The typical depth test consists of placing a surface directly under the glass on one side and a surface at some distance below the glass on the other side. A careful systematic program of research using this technique has been reported by Walk (1966). The visual cliff technique, of course, is applicable only to infants who can locomote and thus usually occurs after 6 months of age. Using the most sensitive of a number of variations of the visual cliff procedure, Walk found that better than 90% of infants at all ages (6½ to 15 months) who respond in the cliff situation do avoid the deep side of the cliff. However, under certain conditions a number of babies who initially choose the shallow side can be coaxed across the deep side. Some of these conditions are: fewer older infants can be coaxed than younger infants, when the pattern under the deep side is more definitive (checks as opposed to homogeneous surface) fewer children can be coaxed across, when the pattern is deeper on the deep side fewer children will cross, depth and definition of pattern are more important for the older infants than the

younger. It would seem therefore that although young infants can make the discrimination between the deep and shallow side, the increased motivation of coaxing can override their normal avoidance of depth. One further point of interest is that older children who can be coaxed across the deep side have had significantly less crawling experience as defined by mothers' ratings of the time at which they started to crawl. Thus although the infants can discriminate, an experiential factor is playing a role in their performance in a depth situation.

Little work has been done directly with infants to ascertain the effective depth cues on the visual cliff. One demonstration (Walk and Dodge, 1962) with a monocular infant indicated that retinal disparity was not a necessary condition for appropriate responding. This result is congruent with the previously discussed results of Fantz.

Bower (1964, 1965a) used the generalization of an operant response to assess the effectiveness of certain depth cues for infants. In the first study (Bower, 1964) 70- to 85-day-old infants were conditioned to turn their heads when a 12-inch cube was presented at a distance of 3 feet. Bower then assessed generalization of this response to a 12-inch cube at a distance of 9 feet, to a 36-inch cube at distances of 3 and 9 feet, and to the original conditioning stimulus. There was most but not complete generalization to the 12-inch cube at 9 feet, next most to the 36-inch cube at 3 feet, and least to the 36-inch cube at 9 feet. This pattern of results is most easily interpretable in terms of amount of change in physical size and physical distance of the stimulus. A change in either size or distance produces a decrement in responding and a change in both (36-inch cube at 9 feet) produces the largest decrement. As Bower points out, these results suggest that such young infants are sensitive to variables specifying distance and size-at-a-distance. In particular, size of retinal image does not seem to be an important determiner of response since when that was invariant (36-inch cube at 9 feet) the least generalization of response occurred. In the second study (Bower, 1965a) these results were replicated with slightly younger infants (40 to 60 days) under monocular viewing conditions. Also in the second study, another group was trained and tested on two-

dimensional pictures of the displays used for conditioning and testing of the other groups. In this latter case there was most generalization in responding in the test condition in which the size and distance of the stimulus was changed, that is, the condition in which the retinal size of the stimulus was invariant. Bower interprets the different pattern of results obtained for this two-dimensional group to imply that motion parallax (a cue available for all the other groups) is necessary to discriminate between the sizes of objects at different distances which project the same size retinal image.

In Bower's situation the change in response with a change in distance of the cube of course implies discrimination of depth. That this is not just due to a change in size of retinal image may be deduced from the fact that a change in size of the stimulus elicits more generalization than a change in size and distance which still leaves the retinal image size the same. In essence, Bower's results imply a degree of size constancy in infants as well as discrimination of depth. Many investigators use size constancy as an indirect way of assessing depth perception under the assumption that it requires that an organism register distance. This assumption may not be true and when possible should be directly verified as in Bower's experiments (see discussion below on relation of size and distance judgments in older children).

In summary, then, infants as young as 1 month appear to discriminate some of the cues which specify depth. Texture and shading appear to be effective cues in eliciting fixation. Binocular parallax is not a necessary cue, but nothing is known as to whether it would be sufficient for infants. Retinal image size by itself does not appear to be a necessary or sufficient cue.

There are two distinctions that can be made in relation to infants' responses to depth. The first is the distinction between preference and discrimination. In any of the preference measures of depth discrimination, failure to respond differentially does not imply lack of discrimination since there are obviously many reasons why a preference might not be manifest even though an organism is capable of discrimination. It is clear that in this case positive results are meaningful but negative results are not.

The second distinction is not as easily stated. It involves the question of whether it can be asserted that infants or animals perceive depth or whether they are simply reacting to cues that are normally correlated with depth. Here the term perceive is used to imply a sense of meaning. This might be considered a purely philosophical question (and indeed one of the authors, A. P., so considers it).

However, there may be a sense in which it is psychologically meaningful. As an example consider a nonverbal organism trained to respond differentially to one depth cue in isolation from others. If this discrimination generalized to all other depth cues in isolation, it could reasonably be argued that the response is made on the basis of the meaning of the cue, that is, depth. This interpretation rests on the assumption that the physical similarity of one depth cue to another is not likely to give rise to so-called primary stimulus generalization. No such experiment has yet been done, but in principle it could be.

Assuming that young infants do respond to depth, this ability may nevertheless improve with age after infancy. Two kinds of studies yield normative data on this question. In one children are directly asked to make distance judgments or matches. In the other children are asked to make size judgments about objects at different distances with the implication that size constancy involves registering of distance—a questionable assumption, as previously noted.

As part of a more general study of the development of space perception, Smith and Smith (1966) asked children ranging in age from 5 to 12 and adults to perform a variety of tasks involving distance estimation. These investigators found that reproduction of distances by children in a free or unreduced viewing condition are as accurate as those of adults. However, under reduced viewing conditions there is improvement with age. This pattern of results may suggest that ability to utilize specific but not necessarily all depth cues improves with age. Alternatively, it may suggest that the redundant depth information provided by ordinary viewing situations is sufficient for even the youngest children to make precise depth judgments.

Studies investigating size constancy usually have shown improvement with age. Typical of these studies is one done by Zeigler and

Leibowitz (1957), who asked Ss to match an adjustable comparison rod 5 feet away to a standard rod whose distance was varied from 10 to 100 feet. The children tested (7 to 9 years of age) showed less constancy than a group of young adults. A somewhat different constancy experiment was conducted by Harway (1963), who asked Ss to generate successive intervals along the ground away from themselves in 1-foot units. A standard foot ruler was placed at their feet as a reference unit. All Ss showed a progressively increasing overestimation of the 1-foot units as the distance away from themselves increased. The younger Ss (5 to 10 years of age) showed considerably more overestimation than did the older Ss (12-year-olds and adults). There was a rather sharp break in performance between the 10- and 12-year-olds. Other normative studies, for the most part showing such improvement in constancy with age, are described in Wohlwill's (1960) excellent review.

One step beyond simply establishing an improvement in size constancy as a function of age is determining which, if any, depth cues change in effectiveness as a function of age. The evidence with respect to retinal disparity as studied by stereoscopic vision is also reviewed by Wohlwill (1960). The data are equivocal: some studies show increased depth responses as a function of age and others do not. Furthermore, the interpretation of some of the studies that do show a change with age is suspect because of the possibility that Ss could not focus on the stereoscopic images (Munn, 1965). One systematic study described by Wohlwill showing an age change is that of Leyer (1939), who presented stereograms tachistoscopically to children 8 to 19 years of age. Here the age trend may have been due to difficulty by younger Ss in focusing or accommodating during a short exposure. Johnson and Beck (1941) found stereoscopic vision present in 2-year-olds. They controlled the light stimulation entering the two eyes by using light differently polarized for each eye and appropriate filters over each eye. The stereoscopic stimulus was that of a doll. The images were projected on a screen an arm's length away from the child. When viewing the stereoscopic images S localized the doll as an adult would, about midway between the screen and himself. When one of the stereo images was turned off S localized

the image on the screen. A best guess at this point would be that stereoscopic vision does not improve with age, at least after infancy. Furthermore, in nonstereoscopic binocular viewing Smith and Smith (1966) found no improvement in depth judgments with age in a relatively rich viewing situation nor in judgments of curvature of a surface in depth under relatively restricted viewing conditions. Thus use of binocular cues in general may not change significantly with age.

There seems to be no information about the use of motion parallax by children. This is surprising in view of a recent interest in self-produced movement as a factor in perceptual development, which will be discussed in connection with the effects of early experience (Section IC). There also seems to be no specific information about the use of convergence as a depth cue as a function of age, in spite of the fact that this cue formed the basis of Berkeley's original empiricist theory. Wickelgren (1967) found a rather variable degree of convergence in neonates presented with pattern stimuli, so it is unlikely that this could be an effective depth cue at birth. Ability to accommodate or focus the lens of the eye does change with age but appears to be at adult level by 6 months (Havnes, White, and Held, 1965). However, no studies have been done on the development of the use of accommodation as a cue to depth.

There is some information about the use of pictorial cues for depth perception. Wohlwill (1962) studied linear perspective. He asked Ss of different ages to bisect a stimulus card presented in a frontal plane. The stimulus outline was the shape of a trapezoid with the narrow end up as would be projected to the eye by a horizontal plane rectangle below eye level. Various stimulus cards were used which had different amounts and regularity of texture. In all cases the texture gradient increased from bottom to top again, which would be the case for a horizontal textured field projected to the eye. All Ss made then bisection judgments too high on the card which would be predicted if they were responding to the linear perspective. In general, then, bias was greater the denser the texture and the more regular the texture, both of these variables presumably provided more perspective information. The adults showed less bias than the children (first, fourth, and eighth

grades) It should be kept in mind that the task was objective bisection of the stimulus card and not bisection of phenomenal depth. Thus, children not only are able to respond to the depth information of linear perspective but apparently are less able than adults to ignore it.

Wohlwill has also directly studied the effects on depth perception of texture uninfluenced by perspective. In one study (Wohlwill, 1963a) he asked Ss to bisect fields extending away from themselves under instructions which set them toward making objective judgments. In another study (Wohlwill, 1965) he had Ss bisect photographic representations of the same fields presented in a frontal plane. In the first study there was increasing overconstancy as a function of age. That is, the adults and older children made their bisections further beyond a true bisection than the younger children. In the second study with photographs Ss of all ages showed underconstancy, but the adults and older children again made their bisections further up than the younger children so at least the direction of age differences was consistent in the two studies. In a very careful review of this general area Wohlwill (1963b) summarizes much evidence for trends toward constancy and overconstancy with age in both size constancy and distance judgments. He further adduces a great deal of evidence to the effect that overconstancy is due to a judgmental or cognitive process. This evidence is compelling but not without exception, and it must be reconciled with the fact that there is little correlation between intelligence and constancy (see Section IVA).

Familiar size as a cue to distance was investigated in a monograph by Smith and Smith (1966). They asked Ss ranging in age from 5 to 12 and adults to judge the distance of a baseball under both reduced and normal viewing conditions. Under the reduced conditions familiar size is presumably the effective depth cue. All Ss overestimated the distance under both viewing conditions, but the adults were more accurate than the children. When the mean values of the judgments under reduced viewing were corrected for the constant error existing under normal viewing conditions (perhaps assuming that it was produced by an artifact in the procedure) the age differences were less consistent but still

seemed to be present. Of course correcting the judgments in this way introduces a conservative bias since the familiar size cue may also be operating under the normal viewing conditions. Thus applying a correction factor from normal viewing could take the effect of the familiar size cue out of the results of the restricted viewing situation.

Smith and Smith also asked their Ss to make size judgments of the baseball. Under reduced viewing conditions about 23% of the children (but no adults) made judgments closer to visual angle matches than to size constancy matches. Under normal viewing conditions only about 7% of the children did this. An important point in this respect noted by the Smiths is that size judgments tended to be bimodally distributed around visual angle judgments and around size constancy judgments. One implication of this is that the grouped data of many constancy experiments lying between size constancy and visual angle matching may be masking two separate distributions conforming rather closely to each kind of judgment.

One final point about such size and distance judgment raised by the Smiths and by Wohlwill (1960) concerns the relation between size and distance perception. The classical size-distance invariance hypothesis is one possible relation. It can be derived from the general empiricist point of view and one way of stating it is that for a given size of retinal image, size and distance judgments should be positively correlated. An empiricist interpretation would be that we know from past experience that a given size of retinal image can be caused by large objects far away or small objects close by. Wohlwill reviews evidence of Denis-Prinzhorn (1961) to the effect that size and distance judgments are positively correlated for children but not for adults. This result is consistent with other studies of adults (e.g., Gruber, 1954). On the other hand, Smith and Smith, correlating size and distance judgments for children and adults in four different tasks, find similar patterns of negative or no relationships for both age groups. Thus the size-distance invariance hypothesis does not seem to hold for adults and the evidence is conflicting for children.

A general view of the work on depth perception suggests that distance perception improves after infancy and there is a trend

toward overconstancy in size judgments. However, there are a number of exceptions to these generalizations which suggest situation-specific determiners of depth perception. There is a lack of systematic work on specific depth cues other than texture gradients. In this case the results are congruent with the preceding generalizations.

The classical empiricist interpretation of certain geometrical illusions is that susceptibility to the illusions depends upon incorrectly perceiving two-dimensional figures as perspective representations of three-dimensional stimuli. The Ponzo illusion (see Table 1), for example, can be attributed to the interpretation by *Ss* of converging lines as indicating depth through linear perspective. This illusion was shown by Leibowitz and Heisel (1958) and Leibowitz and Judisch (1967) to increase with age from 4 to 20 years. Such a developmental increase is predicted by the empiricist position since people are presumed to learn to use perspective cues as a function of experience.

The most recent and systematic exploration of the empiricist hypothesis about illusions is a cross-cultural investigation by Segall, Campbell, and Herskovitz (1963, 1966). Following Sanford (1908), they suggested that illusions such as the Muller-Lyer and Sander parallelogram (see Table 1) depend upon *S* interpreting oblique angles as right angles seen in perspective. To present this hypothesis more concretely, consider the possibility that the Muller-Lyer figures are viewed as representations of sawhorses. The portion of the illusion figure consisting of arrowheads and a line segment would be a sawhorse with the top near *S* and the legs extending away, the portion formed by the arrow tails would be a sawhorse with the top away from *S* and the legs extending toward him. The illusion then is attributed to the possibility that *S* interprets the two equal line segments on his retina as coming from unequal distances. In such a case *S* infers that the one which is further away (formed by the arrow tails) is larger.

In general, such inappropriate interpretations of two-dimensional cues are thought to depend on the degree to which the environment provides stimuli having properties similar to the cues. In particular, the degree to which an *S* interprets right angles as oblique angles seen in perspective (as in the Muller-

Lyer and Sander parallelogram) depends on the degree to which the environment is "carpentered," that is, contains right-angled objects which would project oblique angles to the retina when viewed from most vantage points. Similarly, it was suggested that the horizontal-vertical illusion is a function of the degree to which *S* interprets a vertical line as the foreshortened projection of a line on a horizontal plane extending away from *S*. This in turn was thought to depend on the degree of open horizontal surfaces in the environment. Such an experience-based explanation of these illusions, of course, implies their development as a function of age.

To check this hypothesis, the susceptibility to the Muller-Lyer-Sander parallelogram and horizontal-vertical illusions was assessed in *Ss* from 15 cultures which varied widely in the degree of "carpentering" of environment and in the local geography. These cultures ranged from rural African to urban Western. The data seemed to support to a considerable extent the hypothesis with respect to the Muller-Lyer and Sander parallelogram illusions and to a lesser extent the horizontal-vertical illusion. However, developmental data on the Muller-Lyer illusion from this study and a number of other studies generally concur in finding a decrease in magnitude of illusion with age. Segall, Campbell, and Herskovitz argue that this result is not completely damaging to their thesis since most of the developmental data are from school-age children and by this time the carpentering of the environment may have had its effect.

Pollack (1969) has argued against the empiricist interpretation of the cross-cultural differences in susceptibility to the Muller-Lyer and Sander parallelogram illusions. His suggestion is that anatomical or physiological characteristics such as retinal pigmentation provide a more likely explanation. He supported this suggestion with evidence that *Ss* with higher foveal pigmentation manifest less susceptibility to the Muller-Lyer illusion (Pollack and Silvar, 1967). It may be that differences in foveal pigmentation are a function of environmental factors. Pollack has found an inverse correlation between magnitude of Muller-Lyer illusion reported for the various cultures and a combination measure of the environmental variables: nearness to equator, amount of sunshine, and density of

forest cover. The implication is that these variables are related to density of retinal pigmentation. In short, the argument is that the cross-cultural differences found by Segall, Campbell, and Herskovitz are not a function of the degree of environmental "carpentering" but of differences in retinal pigmentation.

Before leaving the topic of depth perception it is well to consider some evidence that depth information can play an important role in other psychological processes. Several investigations have noted the ease with which children can learn a discrimination between stereometric objects as compared with two-dimensional projections of these objects. Stevenson and McBee (1958), for example, found that children can learn to discriminate among cubes faster than among painted squares or square cutouts. A recent study (Dornbush and Winnick, 1966) investigated whether such differences might not be due to the greater amount of stimulus information provided by three-dimensional stimuli such as perspective information. In one experiment they taught one group of Ss (5- and 7-year-old children) to discriminate between a cube and a parallelepiped of the same depth. A second group of Ss was trained to discriminate between a square and rectangle. The 5-year-olds learned the stereometric discrimination faster than the two-dimensional discrimination. There was no difference for the 7-year-olds. In a second experiment one group of children was taught to discriminate between two-dimensional perspective representations of the stereometric stimuli of the first experiment and a second group of children was again taught to discriminate between the square and rectangle. The 5-year-olds learned to discriminate between the perspective drawings more quickly than between the square and rectangle. Moreover, the absolute numbers of trials to learn the stereometric discrimination and the perspective discrimination were similar, as were the number of trials to learn the pattern discrimination in the two experiments. (Again, no difference was found for the 7-year-olds.) Thus for younger children the perspective information of stereometric stimuli may be an important factor in the ease with which such stimuli are discriminated.

However, there are other differences between planometric and stereometric stimuli

that might also be contributing factors and that should be investigated. These include the motion parallax resulting from S's movement in relation to a stereometric stimulus which is absent when moving in relation to a painted pattern stimulus. It is certainly the case that differences between stereometric and pattern stimuli are easily detected, that is, teaching a child to discriminate between a stereometric stimulus and a painted projection of the stimulus is very easy. It has been shown that this discrimination is easier than the discrimination between horizontal and vertical stripes for rats, infant monkeys, and children (Tighe, 1964; Tighe and Tighe, 1966). Such a stimulus difference can be considered to define a stimulus dimension of three-dimensionality. This dimension appears to be a very prepotent one and deserves more study.

B Development of Shape Perception

It is appropriate to begin a consideration of the development of shape perception in the context of Gestalt psychology with its nativistic emphasis. It is not that empiricists have nothing to say about perception of shape—indeed the same kind of analysis that they make of size constancy can be made with shape constancy. (That is, it could be argued that Ss independently register shape of retinal image and stimulus slant and combine these to yield a veridically perceived shape.) Rather, the Gestalt psychologists contributed some of their most striking ideas to the study of shape perception. In this context the Gestalt laws of organization—proximity, good continuation, symmetry, etc.—were formulated and in this context figural after-effects formed the basis of Gestalt physiology. The Gestalt observation that figure-ground discrimination is a primitive organization of perception has often been applied to shape. For example, a contour is seen as belonging to the figure and not to the ground and the ground is seen as continuing behind the figure. The position holds that we see things the way we do because our brain functions in a certain way. The Gestalt laws of organization, for example, are thought to reflect the biases of brain processes as they interact with particular patterns of stimulation. Thus a "good form" such as a circle will be seen under more rapid tachistoscopic exposure or will be remem-

bered for a longer time than would an irregular polygon. In any case, shape perception, except in a very restricted way (e.g., figural after-effects), should not depend on prior experience.

Shape perception in infants has only recently been directly studied. Fantz (1963, 1966) employed his preference technique first to show that infants, even neonates, could discriminate between complex forms. He, as well as a number of other investigators, varied the stimuli presented to the infant to determine the stimulus dimensions to which they were attending. The reader is again referred to the chapter by Kessen for a thorough discussion of this work and to the section on attention (VI) of the present chapter for additional consideration of these studies.

Bower has employed measures of response generalization to assess directly the function of certain Gestalt laws in infancy. In one study (Bower, 1965b) he used inhibition of an unconditioned sucking response to a "surprising" stimulus as an index of an infant's sensitivity to perceptual unity. For example, infants were shown a pair of vertical rods moving together from side to side. After they had been habituated to this and no longer ceased sucking upon presentation of the display it was changed. Now the rods moved toward and away from each other. For one change the height-separation ratio of the rods was kept constant so they projected the image of a rigid pair of rods approaching or receding from S. For the second change the rods had constant height so they project an image of two objects moving together and apart. This latter image of a previously rigid configuration of two rods might be surprising as a disruption of "common fate." The sucking rate of 10-week-old infants was in fact significantly suppressed when they were shown the second display change as compared with the first. Two other displays constructed on analogous principles to exemplify the Gestalt properties of proximity and continuation did not result in differential responding until 40 weeks of age. In a second study Bower (1967) again used the generalization of an operant response and was able to show that good continuation may be an effective shape variable for 5-week-old infants, although simple proximity still was not. These imaginative

experiments of Bower are excellent demonstrations of techniques for investigation of complex perceptual problems in infants. However, the particular choice of stimuli permit alternative explanations and the small number of stimuli limit the generality of the results, thus restricting the theoretical implications.

Bower (1966) has reported a somewhat more systematic exploration of shape constancy in infants. This study again employed generalization of an operant response, in this case head turning. The experiments involved conditioning an infant to respond to a particular shape at a particular slant, then testing for generalization to stimuli which (1) were physically the same shape, but were at different slants and projected different retinal images, (2) were physically different shapes but were at the same slant and projected different retinal images, and (3) were physically different shapes and were at different slants but projected the same retinal image. In all the experiments the first condition elicited the most generalization, that is, there was shape constancy. On the basis of these data Bower argues quite convincingly that the empiricist position of independent registry and subsequent combination of shape of projected images and slant must be incorrect. He concludes that infants are set to respond to higher-order invariants specifying shape-at-a-slant and that they ignore the lower-order invariants of simple slant or image shape.

It is clear, in summary, that infants, even as neonates, can discriminate among some aspects of shape. Just what the stimulus determinants are is not always clear. The work of Bower certainly suggests that infants respond to some very complex parameters of shape, but much more systematic work is needed before the nature of these parameters is understood. Some other possibilities will be considered in connection with the discussion of attention.

Considerable work has been done on various Gestalt factors in shape perception with older children. There have been several studies of figure-ground relations in children. Weiner and Strauss (1941) and Dolphin and Cruikshank (1951), for example, examined the possibility that figure-ground differentiation was poorer in retarded children than in normals. Their results suggested that brain-damaged children (but not all retardates) are

more oriented to ground than normal children, who are figure oriented. Spivack (1963) has suggested that these results may be due in part to the use of a different response criterion by the brain damaged. He himself (Spivack and Levine, 1959) provides some evidence that brain-damaged children show less reversal than normal children in stimuli with ambiguous figure-ground relations such as the Necker cube and the Schroeder staircase.

Elkind and Scott (1962), using a greater variety of ambiguous figures with children in nursery school and first, second, and third grades, found an increasing ability as a function of age to name alternative figures of the stimuli. They also found a correlation of .43 between IQ and number of figures named. Botha (1963), studying nursery school children, looked at the effect of pre-exposure on the reversal of an ambiguous figure. The stimulus could be seen either as a black figure on white ground or a white figure on black ground. The children were pre-exposed predominantly to one or the other of the two alternative ways of organizing the stimulus. Then they were shown the ambiguous stimulus. They reported seeing the alternative presented less often in the pre-exposure. This was also true of semiliterate natives but not of educated adults. The latter always reported seeing the black-on-white alternative, which the author attributes to long experience reading black print. Elkind, Koegler, and Go (1962) also conducted a pre-exposure experiment with ambiguous figures. This study was in fact a training experiment with 6-, 7-, and 8-year-olds. They were shown one set of ambiguous figures as a pretest, then a second set as a training set of figures, and finally the original set of figures as a posttest. The children were asked in the tests to report what they saw while looking at the ambiguous figures. Training consisted of giving successively more complete clues as to what the alternative organization of the figure might be. The children of all three ages improved from pretest to posttest in the number of figures named and they retained this improvement over a 1-month interval. In addition, there were significant age differences in both the pretests and posttests, with the older children reporting more figures than the younger. However, this experiment was weak insofar

as there was no control group to assess the effect of repeated presentation of the stimuli on pretest and posttest without the intervening training.

Other investigations of children conducted in the Gestalt tradition include studies of embedded figures, part-whole identifications, and identifications of incomplete figures. Ghent (1956) conducted an investigation of the ability of children 4 to 8 years old to identify overlapping and embedded figures. When overlapping figures represented real objects, the children named the objects, when they were overlapping geometric figures the children identified the objects from an array, and when embedded figures were used the children had to trace out the hidden figure which matched the sample given them. Reliable age differences were found, with the older children being able to make more identifications than the younger. In addition, the children found the embedded figures more difficult than the overlapping realistic figures, which in turn were more difficult than the overlapping geometric figures. This result must be accepted with caution because of the differences in procedure among the three tasks and lack of control for order effects.

✓Part-whole identification in children has been studied by Elkind, Koegler, and Go (1964). They showed children figures which consisted of objects arranged to form larger objects. For example, candy canes were arranged in the shape of a scooter. The child was asked to describe each figure and was scored on whether he mentioned the parts only, the whole figure only, or both parts and whole. "part" responses dropped from 71% at 4 years of age to 21% at 9 years of age. Over this age range "whole" responses vary from 17 to 0%, while "part and whole" responses increase from 11 to 79%. On the surface these data do not seem to support the Gestalt view that perceptual development proceeds from global to analytic or that stimuli become more articulated. However, in such studies it is very difficult to control for the specific properties of the stimuli comprising the parts and the whole—their meaningfulness, their discriminability, etc. Thus it is difficult to make unequivocal interpretations of the results.

The perception of incomplete figures has been compared in children and adults in a

series of studies by Gollin (1960b, 1962, 1965) In various experiments he showed Ss ranging from preschoolers (2½ years) to third graders and adults incomplete pictures which were made by eliminating large portions of the contour of line drawings of objects such as a shoe Their task was simply to identify the picture In one experiment successively more complete pictures were presented until S was able to identify the picture correctly In other experiments only the most incomplete picture was ever shown In general, as would be expected, the older Ss performed better than the younger Ss For example, in one study the correlation between recognition ability and CA was .66 In many of the experiments Gollin was interested in training Ss to improve their recognition scores Typically the training involved pre-exposure (naming or serial learning) to the complete outline figures or moderately incomplete figures and then testing for effect of training with very incomplete outlines of the same figures The adults benefited more than the children when the training was on the complete outline figures, but there was no age difference when the training was on the moderately incomplete figures This interaction between the variables of figure completeness and age might be due to the fact that there is a greater difference between the training stimuli and test stimuli when the complete figures are used for training than when the moderately incomplete figures are used Older Ss with higher MA may be able to make this transfer better than younger Ss

Some support for this hypothesis is found in another experiment in which Gollin found that Ss with higher IQ or higher CA were able to recognize the incomplete figures better after training on the complete figures Potter (1966) has studied the recognition of figures impoverished by blurring rather than deletion although not from a Gestalt-theoretical point of view The emphasis in this study was on cognitive factors in recognition In general, adults recognized figures with more blurring than did children However, older children and adults, perhaps because of more integrated responding, were more hindered by forming early hypotheses about the nature of a blurred figure than were younger children The older Ss required relatively more focus-

ing of the figure than did younger Ss after an incorrect hypothesis had been made

One additional study of Gestalt properties should be mentioned This is a study by Graham, Berman, and Ernhart (1960) of the ability of preschool children to copy forms Children 2½ to 5 years were asked to copy various forms including a straight line, a diamond, and other curved and straight line figures Each reproduction was judged on whether it was more or less "primitive" than the original in terms of Werner's (1957) criteria of simplification, increased closure, and increased symmetry As Werner would predict, simplification and increased closure were more common in younger children than in older, but so were their opposites, complication and decreased closure (or opening) of the figures There was more increase of symmetry in the younger children than in the older, which is also in accord with Gestalt expectation The reproductions were also judged for accuracy on several characteristics form, curvature or linearity, openness or closedness, orientation, size relationship of parts, and accuracy of intersections There was improvement in accuracy for all these characteristics as a function of age The authors conclude that such a simple quantitative change of accuracy is a better description of improvement than a change in the Gestalt properties Although there have been numerous studies of children's ability to copy forms using the Bender Gestalt test, by and large these studies have not broken down the results by type of error (e.g., Koppitz, 1960) Where the results have been so classified (e.g., Quast, 1961), the scoring categories have not for the most part been relevant to Gestalt properties However, these scoring categories may have intrinsic merit and the reader is referred to Quast (1957, 1961) for such an analysis

It is clear from a consideration of the various studies in the Gestalt tradition that there are developmental changes better identification of the alternative organization of reversible figures, better identification of embedded figures, more identification of the parts and the whole of stimulus configurations, and better recognition of incomplete figures Although many of these studies are intrinsically interesting, the general implications of the results are not really clear since

the relevant stimulus dimensions are not clearly specified. This has been the traditional problem with the Gestalt properties and it has not been solved in these studies with children. There have been some provocative attempts at such specification with adults. For example, Hochberg and McAlister (1953) and Attneave (1954) independently suggested an information theory metric that may define the property of good organization. Hochberg and Brooks (1960) used a variation of this measure to predict whether ambiguous figures would be seen as two- or three-dimensional. Using children as Ss, Hochberg and Brooks (1964) also showed that this measure predicted which of several two-dimensional representations of a geometric solid would be chosen as most like the real solid. However, no direct age comparisons of the predictive value of this measure have been made. Such comparisons would be quite interesting.

Not all investigation of the development of shape perception has been done in the Gestalt tradition. There have been at least two other types of investigation. One, conducted most systematically by Soviet psychologists, is an examination of the perceptual activity of S while he is identifying or discriminating shapes. In a series of studies conducted in Zaporozhets' laboratory, Zinchenko and other colleagues (Lavient'eva and Ruzskaya, 1960, Tarakanov and Zinchenko, 1960, Zinchenko, 1957, 1960, Zinchenko, Chzhitsin, and Tarakanov, 1962, Zinchenko, Lomov, and Ruzskaya, 1959, Zinchenko and Ruzskaya, 1960a, 1960b) investigated the eye movements involved in visual discrimination of shape and the hand movements involved in haptic discrimination of shape. These studies of children from 3 to 7 years have been reviewed elsewhere (Pick, 1964). It should be noted here, however, that at very young ages, when shape identification was poor, children tended to concentrate their eye or hand movements around the interior of objects and the movements had little relation to the shape. At intermediate ages the movements of the receptor organs conformed rather closely to the contour of the shape. With older children the movements became very abbreviated, they included points on the contour but jumped quickly around and did not at all trace the contour. It also is interesting

to note that these investigators started with the Berkeleyian idea that touch teaches vision but were forced by their data (precise identifications earlier by vision than by touch) to reject this hypothesis.

A second type of study of the perceptual development of shape not in the Gestalt tradition is one exemplified by Gibson, Gibson, Pick, and Ossei (1962). In such studies the stimuli are constructed so that inferences can be made about the perceptual process from an analysis of the discrimination errors. This study by Gibson et al. was conducted as part of a project investigating basic processes involved in reading, and its immediate goal was to trace the development of children's ability to discriminate letterlike forms. An analysis of printed capital letters was made and a set of standard nonsense line drawings was constructed following various constraints found in the real alphabet. For each standard form four classes of transformation were generated: rotations and reversals, changes of straight lines to curves and vice versa, topological transformations (adding or subtracting a piece to the standard), and perspective transformations (tilting the standard and reproducing the projected view). The children were shown a standard form and an array containing the transformations and some exact copies of the standard. They were asked to pick out all forms identical to the standard. Children at all ages (4 to 8) tended to confuse the perspective transformations with the standard and few children at any age tended to confuse topological transformations with the standard. Rotations and reversals and line-to-curve changes were confused with the standards by the young children but not by the older children. The greatest improvement in these latter discriminations came around 5 to 6 years when the children were presumably learning to read in school. The authors suggest that the kinds of discrimination the child was making in his everyday life transferred to form discrimination. This hypothesis, admittedly post hoc, accounts for the results quite well, although it should be recognized that the particular values of the specific transformations of the standard (e.g., perspective transformations were projected views of standards tilted 45°) might have affected the results. The hypothesis is particularly interesting in two respects. It suggests that children

transfer perception of *critical features* from one situation in their environment to another and in fact to a completely novel situation (see also Section VIC) It also suggests that transfer occurs easily from three-dimensional to two-dimensional stimuli

Another experiment in which inferences about the perceptual process are made from errors in discrimination is one reported by Kerpelman and Pollack (1964) In this study 4-, 5-, and 6-year-old children had to select from a circular array of shapes one that was identical to a standard shape in the center One hypothesis investigated was that children of different ages might respond on the basis of different parts of shapes The shapes were either irregular pentagons or only the tops, bottoms, or centers of these pentagons In all conditions performance improved with age and for all ages bottoms were easiest to identify and centers most difficult The easy identifiability of the bottoms may have implications for certain hypotheses about scanning behavior in shape perception For example, Ghent (1961a) has argued that children tend to scan shapes from top to bottom (see Section IIIB) and the present results might seem inconsistent with that hypothesis However, it is difficult to generalize confidently from these data without a careful analysis of the differences between specific shapes, perhaps the bottoms are more different from each other than the tops

Research on the development of shape perception (as well as on shape perception in adults) is hampered by a lack of a good metric for shape This is especially important for inferences about shape perception from error analysis since such analysis depends on the relation between shape differences and errors If the stimulus differences are not quantifiable or if they are not psychologically meaningful, they are not likely to advance our understanding The shape differences in the study by Gibson, Gibson, Pick, and Osser seemed to be psychologically meaningful Other recent studies of shape perception have used stimuli generated on the basis of concepts from information theory These shapes have certain mathematical properties but the differences between them may not be relevant to the differences between shapes in the real world Finally the obvious comment should be made that the two approaches—the focus

on receptor organ activity and error analysis in the study of shape perception—should be combined Not only could the results of one procedure verify the conclusions of the other, but by showing points of inconsistency further insight into the process of perception would be gained [For a general theoretical analysis of the problems of shape perception the reader is referred to Uhl's (1963) discussion of the problems encountered in computer recognition of shape]

How does shape perception interact with perception of other stimulus attributes? Recently there has been considerable interest in the relation between color and form perception The problem has focused on the old observation of Brian and Goodenough (1929) that younger children match stimuli on the basis of color rather than form and older children do the opposite The methodology of older studies of this phenomenon has been improved and the effects of such stimulus dimension preferences on learning have been explored

The two currently most active researchers in this area are Corah (1964, 1966) and Suchman (Games, 1964, Suchman, 1966, Suchman and Triabasso, 1966a, 1966b) Corah has been interested in the possibility that the color preferences typically found for young children may be based on a difference in attention between younger and older children It may be more difficult for a young child to attend to the contour of a figure than to the whole colored configuration In one study (Corah, 1966) this hypothesis was investigated by varying the amount of color and complexity of contour It was reasoned that if the amount of color was reduced, the preference would be reduced and if the complexity of the contour was increased, the preference for color would be increased since the complex contour would be more difficult to apprehend A group of young children ($4\frac{1}{2}$ years) and a group of older children ($8\frac{1}{4}$ years) were given a matching-to-sample task The sample form was presented above two comparison forms One matched the sample in shape and the other in color The child's task was to pick the comparison stimulus most like the sample Three types of problems were presented (1) the shapes were very simple and very different (e.g., square and circle), (2) the shapes were simple but the comparison

shapes were similar to the sample (e.g., a square and rectangle), and (3) the shapes were complex (pentagons) and the comparison shapes were similar to the sample shapes. In all three problems the colors were red, blue, and green but for half the problems the shapes were solidly colored and for half the problems just the outlines of the shapes were colored. As hypothesized for the younger children, there were more color responses with the solid colored and more complex shapes. However, overall these children made more form than color responses. For the older children there were no color responses under any of the conditions.

Suchman has been interested in the relation between color-form preference and ability to discriminate. In one of her studies Suchman (1966) compared 7- to 12-year-old hearing and deaf children. One of the two preference tests involved comparisons of three stimuli that varied in color, shape, and size. The stimuli were so selected that any pair had the same value on one of these dimensions but differed on the other two. The S's task was to choose the stimulus of the three he considered to be different.² In both this test and a sorting test of the Weigl or Goldstein-Scheerer type the hearing children displayed a preference for form and the deaf children for color. Furthermore, in discrimination tests of color and of form the hearing Ss discriminated form more accurately than the deaf Ss and the deaf Ss discriminated color more accurately than the hearing Ss. Although this seems to support a hypothesis of relation between preference and discrimination accuracy, the results of a direct comparison between children (both deaf and hearing) who preferred form and those who preferred color did not show a statistically significant relation between their preferences.

² It should be pointed out that this procedure involves asking Ss to attend to differences between stimuli, whereas the more traditional matching-to-sample procedure involves Ss attending to similarities. Although these procedures may be logically equivalent, they may not be psychologically equivalent. It is possible that an S will attend to different stimulus dimensions when asked to look for similarities than when he is asked to look for differences. This possibility should be kept in mind when interpreting dimensional "preferences."

and accuracy of discrimination. Also, no relation was found in this study between color or form preference and performance in a discrimination learning problem in which the relevant cues were color or form. However, in another study (Suchman and Triabasso, 1966b) with 2- to 6-year-old hearing Ss such a relation was found. That is, color or form preference facilitated learning when the preferred dimension was the relevant one.

The difference in preference between deaf and hearing Ss is quite interesting since it suggests a very unexpected influence of early sensory deprivation on saliency of stimulus dimensions. This is a reliable result replicating an earlier study (Gaines, 1964), and it is not based on intellectual differences since the hearing and deaf children were matched for IQ and age. The underlying explanation for this difference in preference is not clear.

In spite of the interest in the relation between stimulus dimension preference and discrimination ability no one investigating such preferences has equated the discriminability of the stimulus differences on the basis of psychophysical experiments. If the young child's color preferences and the older child's form preferences merely reflect greater discriminability of the preferred dimension, the results are somewhat less interesting than if a preference is manifest independently of discriminability. It is also the case that most of the preference studies have utilized only a few colors and shapes. These dimensions should be sampled widely in order to generalize the results to color and form as stimulus dimensions. However, there are large numbers of studies using slightly different procedures, forms, and colors which typically find a greater degree of form preference in older children. Such consistency argues that this preference is a real one and not an artifact of the particular stimuli used. Quite interesting but not so consistently reported is the observation of a shift from form to color preference at a very early age (Brian and Goodenough, 1929).

Another stimulus dimension preference has been observed by Klein (1963). He noted that in tactual matching young children tend to match stimuli on the basis of texture, whereas older children tend to match on the basis of shape. Again the texture differences and the shape differences were not equated for dis-

criminability and the results are limited to the shapes and textures used in this one study since no other work has been reported

Tactual perception of shape is a problem that has recently elicited considerable interest. One type of tactual problem is analogous to the overlapping and embedded figures studied in the context of visual shape perception. Gollin (1960a, 1961) asked children and adults to discriminate tactually a figure made up of tacks placed in plywood. Their task was to indicate whether two figures were the same or different. In half of the pairs the figures were masked by having tacks of a different size placed at random around the basic figures. The remaining pairs were unmasked figures, that is, just the tacks defining each figure were present. Adults were better than first- through third-grade children at discriminating both types of figures. Masking the figures resulted in a decrement in the children's performance but not in the adults' performance. Also, adults and older children showed facilitation in discriminating the masked figures after tactual experience with the unmasked. The greater ability of older Ss in this task is similar to that found by Ghent (1956) for visually embedded figures, as has previously been discussed.

Other developmental studies of tactual shape perception have investigated stimulus properties in relation to shape discrimination. Hermelin and O'Connor (1961) used unfamiliar Greek and Russian letters in tactual and visual matching tasks. They found that retarded children were more accurate tactually than visually. Medinnus and Johnson (1966) failed to replicate this result, however, so the status of this finding is unclear. Soviet investigators (Lavrent'eva and Ruzskaya, 1960, Tarakanov and Zinchenko, 1960, Zinchenko, 1957, 1960, Zinchenko, Chzhitsin, and Tarakanov, 1962, Zinchenko, Lomov, and Ruzskaya, 1959, Zinchenko and Ruzskaya, 1960a, 1960b) have examined tactual discrimination tasks again in relation to response processes. Their conclusions for the development of tactual perception of planometric stimuli are similar to those for visual shape perception. Younger children are quite inaccurate and their exploratory movements do not conform to the contour of objects. As their exploration becomes more systematic the number of errors decreases. This improvement

occurs at a slightly older preschool age than with visual perception of the same shapes. However, the improvement in tactual perception never reaches the same level as visual perception during the preschool years.

The later development of tactual shape perception was the subject of a study by the present authors (Pick and Pick, 1966). This was a tactual replication of the study of Gibson et al. with letterlike forms. The forms were raised line drawings on a metal background. The children were blindfolded and explored the shapes simultaneously in pairs, each consisting of a standard form and a transformation. The Ss were children from 6 to 13 years of age and adults. The tactual perception of these forms was much more difficult than the visual perception of the forms. Even adults made an appreciable though smaller number of errors than the children. At all ages the perspective transformations were confused with the standards most often and the topological transformations least often. The line-to-curve transformations were of intermediate difficulty. These results are similar to those for visual perception of the forms. The main difference between the visual and tactual results was with the rotations and reversals. These were as easy to discriminate tactually from the standards as were the topological transformations. This is reasonable if one considers how the child is exploring the stimuli. He typically moves his two hands over the two forms synchronously. A rotation or reversal of a form would be equivalent to a topological transformation in that the child is likely to find parts added or missing in corresponding places explored by the hands.

In general, very little work has been done in studying the development of tactual shape perception. Furthermore, the stimulus dimensions varied have been derived from visual studies and so a good metric for shape is lacking in tactual perception. In addition, it is not clear that the same shape dimensions are psychologically meaningful for both sensory modalities. An imaginative analysis of the shape dimensions psychologically important in tactual perception is needed. No work has been done with tactual shape perception of infants. One might speculate that infants would be particularly sensitive, for example, to the shapes of nipples, although tactual sensitivity

of the mouth and tongue is not often studied.

The studies of the development of shape perception concur in finding that tactual perception develops more slowly and is less accurate than comparable visual performance. These findings place an additional burden of proof on empiricist theoretical statements that visual perception is dependent on prior tactual perception.

Effects of Early Experience on Perception

The nativist-empiricist controversy receives most precise definition in studies manipulating early experience. With such direct study the interactive relation between heredity and environment also becomes most clear. Of course manipulation of early experience is a procedure most generally applicable to animals (See Chapter 12 for a more general discussion of this area). However, in some cases mild or enriching manipulations can be undertaken with children, or advantage can be taken of pathologies such as congenital blindness or deafness to study the effects of early experience in humans. Generally speaking studies manipulating early experience can be divided into deprivation or enrichment studies. In addition, some investigators have suggested that perceptual rearrangements (distortion studies) provide information analogous to that from early experience studies. Studies of experimental manipulation in the environments of animals and their effects on perceptual development will be considered first and then the effects of early experience on human perceptual development.

Studies of the effects of early experience shape perception have often used an enrichment design. Animals raised in a "natural" environment have been compared with animals raised in an "enriched" environment in subsequent ability to discriminate shapes. The basic question, of course, is whether any such enrichment is effective at all. Other important problems include the question of the existence of a critical period for the effects and the question of specificity between the early stimulation and the subsequent effects.

In one series of studies Gibson and Walk and their students (Gibson and Walk, 1956, Walk, Gibson, Pick and Tighe, 1958, Gibson, Walk, and Tighe, 1959, Walk, Gibson, Pick, and Tighe, 1959) conducted a total of nine

different experiments. All of these were variations of a design which involved early exposure of rats to triangles and circles. In the first study of the series (Gibson and Walk, 1956) triangles and circles cut out of sheet metal were hung on the sides of the cages during rearing. This exposure markedly facilitated subsequent discrimination learning between triangles and circles. (These were painted on the doors of a Grice discrimination apparatus, which presented on each trial two alternatives at the end of an alley.) With this strong effect as a basis the investigators began a series of studies focusing on other variables such as the role of reinforcement, the timing of exposure, and the specificity of the exposed stimuli to the subsequently learned discrimination. In conducting these studies replications of the original study which were included in the designs frequently did not produce the original results. Examination of all the studies revealed that whenever the original results were replicated the pre-exposure forms were cutouts on the sides of the animals' cages. All failures to replicate occurred when the pre-exposure forms had been modified so that they were painted on a background. The authors suggest that the essential difference between the cutouts and painted forms was the presence of motion parallax when animals moved with respect to the former but not the latter. Possibly this parallax attracted the animal's attention to the edge of the form.

Because of the only intermittent success in replicating the original phenomenon during the series of studies, many of the follow-up experiments investigating other questions did not produce informative results. Those experiments investigating specificity of the early experience suggest that the facilitating effect generalizes over a wide range of stimuli. It was also determined that facilitation of triangle-circle discrimination would occur with only one of these as the pre-exposure form and it made little difference whether it was the subsequently positive or negative stimulus in the discrimination learning. Recently Kerpelman (1965) investigated the role of reinforcement using a design which also included a replication of the original Gibson and Walk experiment. His results indicated that reinforcement, eating in the presence of

the stimuli, did play a role, even though differential reinforcement of the positive and negative stimuli did not occur.

In two experiments Forgas (1958a, 1958b) adduced additional evidence that early exposure of rats to outlines of forms facilitates later discrimination between them. The results of his experiments suggested that facilitation in the discrimination did not occur for forms identical to those pre-exposed but rather to variations of the original forms. For example, pre-exposure to the sides of a triangle without the angles markedly facilitated later discrimination of a complete triangle from a circle. This was not true when pre-exposure was to the complete figures. These results show the effect of early experience by capitalizing on the animal's response to a novel aspect of stimuli. It seems to be important that the novel aspect be of high information value such as angles.

In a broad sense studies of imprinting might be considered to demonstrate the effect of early enriching experience on later perception. These will not be reviewed here, the reader is referred to Chapters 6 and 12 for discussion of this phenomenon.

The deprivation technique for the study of effects of early experience is typified in a study by Riesen and Aarons (1959) which demonstrates the effect of visual deprivation on a subsequent visual discrimination. These investigators raised kittens in darkness for the first 6 weeks of life. Then they were subdivided into groups which were given (1) 1 hour per day of diffuse light stimulation without head movement or (2) 1 hour per day of pattern stimulation without head movement or (3) 1 hour per day of pattern vision with freedom of movement, or (4) normal rearing in the laboratory environment. All animals were trained between 14 and 18 weeks on a discrimination between a stationary and moving form and a brightness discrimination. The animals in all four groups were able to learn the brightness discrimination, but the animals who had pattern stimulation with free movement, groups (3) and (4), were vastly superior in learning the discrimination between stationary and moving form. Examination of the eyes of all the animals suggested that the peripheral parts of the visual system were unaffected by the differential rearing, as did the

fact that they all could learn the brightness discrimination. The critical factor appeared to be the possibility of movement in the presence of patterned visual stimulation and the deficit caused by the absence of this experience seemed to be central in nature.

The importance of movement, particularly *self-produced* movement in the presence of visual stimulation, has also been implicated in the development of depth perception. Held and Hein (1963) raised kittens in the dark until the age of 8 to 12 weeks. At this time they were exposed to visual stimulation for 3 hours per day in the following manner. An experimental and a control kitten were linked together at opposite ends of a pivoted bar. The bar was set inside a vertically striped cylinder and the kittens were harnessed in such a way that every movement that the experimental animal made pushed the control animal through an equal distance. The control animal was raised off the floor so it could not move itself. However, it was exposed to exactly the same changes in pattern of visual stimulation as was the experimental animal. The difference was that the changes were correlated with the movements the experimental animal was making. (This design epitomizes the yoked control.) Kittens were tested daily for visually guided paw placement (i.e., reaching out toward an approaching surface), and as soon as the experimental kitten made a paw placement both kittens of the pair were tested on a visual cliff. All experimental animals developed a paw placement to an approaching surface and a blink response to an approaching hand before the corresponding control animals. At the time of visual cliff tests all experimental animals made appropriate depth responses, that is, they chose the shallow side on all trials, but the control animals responded at an approximately random level. The initial inability of the control animals to make a paw placement is congruent with observations made by Riesen and Aarons on the kittens which were raised without the opportunity to move in the presence of patterned stimulation.

Held and Hein's study and nearly all the other studies of the effect of early experience on depth perception have used the method of deprivation rather than enrichment. Many of these studies have utilized the visual cliff

The first of these studies of performance on the visual cliff compared dark-reared and light-reared rats on their preference for the shallow side of the cliff. In these studies (Walk, Gibson, and Tighe, 1957, Walk and Gibson, 1961) in which rats were raised in the dark for 90 days and then tested in a simple cliff situation no differences in preference were found between the normally reared animals and the dark-reared animals. However, subsequent studies (Nealy and Riley, 1963, Walk, Trychin, and Karmel, 1965) extending the dark-rearing period of rats to 140 or more days found a failure of depth discrimination on the cliff. The effect was not irreversible, after 2 weeks of exposure to light the animals began to discriminate depth.

✓ Walk and Gibson (1961) also raised kittens in the dark until the age of 26 days. In contrast to the rats reared 90 days in the dark, these animals seemed functionally blind when they were placed on the visual cliff. They stumbled around, falling off the center board of the cliff indiscriminately to either side. They made no placing responses or tracking response of moving objects. Their only visual response was a pupillary reflex to changes in illumination. During several days of living in light their visual cliff behavior and paw placement gradually indicated depth discrimination. In contrast, control light-reared kittens showed good depth responses on the cliff and accurate paw placement. Thus the visual development of a kitten seems much more sensitive to early manipulation than that of the rat.

That early experience can affect the rat's visual development is demonstrated in more analytic experiments of Walk and Gibson (1961). In these experiments they investigated the effective depth cues on the visual cliff for light- and dark-reared rats. The typical cliff situation was modified in two ways. First, real differences in depth were eliminated by placing both visual surfaces directly underneath the glass. Differences in texture density of the retinal image were preserved by making one surface pattern so fine that it projected to the eye approximately the same sized pattern elements as the surface usually at the deep side of the cliff. In the second modification real differences in depth were preserved. Differences in texture density

were eliminated by making the elements of the pattern of the deep side of the cliff so large that they projected the same sized elements to the eye as the elements on the shallow side. Normal light- and dark-reared rats were tested in both these conditions. The light-reared rats made appropriate depth responses under both conditions; they chose the coarser textured pattern when depths on both sides were equal or they avoided the actual deep side when texture density differences had been eliminated. The dark-reared rats, however, responded to the real depth differences but not to the texture density differences with equated depth. The authors suggest that the effective cue for the dark-reared rats is the differential motion parallax present with real depth differences between the two sides of the cliff. For the light-reared rats both texture size and motion parallax are effective cues. The authors speculate that texture size may be a learned depth cue by virtue of its association with motion parallax. They do show that the preference for the larger texture size does develop gradually in dark-reared rats after they have been brought out into the light.

It has been found possible to modify the typical preference for the shallow side of the visual cliff. In two studies animals were raised on the deep side of a visual cliff and this experience tempered their visual preferences for the shallow side. Tallicaro and Farrell (1964) found that 35 hours of rearing chicks on the deep side of a visual cliff eliminated the usual preference for the shallow side. In fact, there was a slight but not statistically significant preference for the deep side. Kaess and Wilson (1964) found that 2 weeks of rearing rats on the deep side of a visual cliff reversed the typically found preference for the shallow side. Although the possibility of thus modifying a preference is very exciting, it says little about whether the animal innately discriminates depth. It certainly does not, as Tallicaro and Farrell suggest, cast doubt on whether animals innately avoid a cliff.

For obvious reasons, deprivation of early perceptual experience is not often undertaken with humans. However, studies have been conducted of naturally occurring deprivation, for example, of congenitally blind Ss whose sight has been restored. Senden (1960) re-

viewed a large number of cases derived from a variety of sources extending from medical reports to newspaper articles. Hebb (1949) interpreted these cases to show that such patients have considerable difficulty in perceiving or learning to perceive shape. However, Wertheimer (1951) has criticized his interpretation and indeed Hebb himself acknowledged the difficulty in making such use of nonscientific sources. More recently Gregory and Wallace (1963) carefully examined a 53-year-old man whose sight had been restored. This patient, who had been blind from the age of 10 months, was able to identify visually certain shapes soon after the operation. These were shapes he had been familiar with tactually, for example, upper-case printed letters. He was not able to identify complex shapes such as the expression in people's faces, and his susceptibility to geometric illusions was very low. No mention was made of any difficulty in identifying visual direction. If a capacity for identifying visual direction by pointing is present in persons with restored sight, a means is provided for intermodal transfer of shape perception from touch (or kinesthesia and proprioception) to vision. The shape of objects seen visually could be traced out and the response could be made to the tracing movement. It might also be possible to perceive the shape without actually making the movement since the information for the movement is present.

Gregory and Wallace's patient saw objects in depth, although his distance scale was somewhat distorted. On the other hand, he saw no depth in two-dimensional line drawings representing three-dimensional objects such as the Necker cube and the Schroeder staircase. This might suggest that visual experience is necessary for seeing depth in such stimuli. However, Hudson (1960) provided evidence that South African natives who had not attended school were also deficient in seeing depth in line drawings.

Is the ability to recognize (as distinguished from seeing depth in) two-dimensional representations of objects, in general, dependent on experience with such representations in our highly pictured world? Hochberg and Brooks (1962) performed the herculean task of raising their son to the age of 19 months

in the absence of two-dimensional representations of objects. At this age his recognition of photographs and other two-dimensional representations of objects was tested and proved to be excellent. Zimmerman and Hochberg (1963) reported a similar experiment with monkeys. Infant monkeys were taught an object discrimination and displayed considerable transfer to photographs of the objects. As the photographs were impoverished in various ways the amount of transfer decreased.

The role of early visual experience on tactual perception can be investigated by comparing the tactual perception of blind and sighted Ss. The relevant data from such experiments has been summarized by Pick, Pick, and Klein (1967) and will not be reviewed here. Most of that work has addressed the problem of shape perception and this may bias the results toward showing a considerable effect of early visual experience. Early visual experience might not effect the tactual perception of texture, for example. There is a commonly held view that visual experience markedly influences one's imagery even with nonvisual perception. Although this may well be true, there is little experimental evidence on the question.

The enrichment technique for investigation of perceptual effects of early experience has not been widely employed with human Ss. White (1968) has enriched the environment of institutionalized infants in particular ways such as increasing the amount of handling by 20 minutes per day in one case and introducing into cribs specific attention attracting objects in another case. He found specific perceptual effects, for example, on the amount of looking behavior and the age at which their hands are noticed. His manipulations, carried out against the background of very careful normative observations, show the power of this combination of techniques. The various educational intervention programs being conducted widely in this country also involve enrichment procedures but, by necessity, the nature of the intervention and analysis of effects are not very specific. If such massive enrichment can be demonstrated to have substantial effects, it is hoped that analytic investigations will be undertaken to determine the specific causes and effects.

II BASIC SENSITIVITY IN CHILDREN AND PSYCHOPHYSIOLOGY OF PERCEPTUAL DEVELOPMENT

A. Visual Sensitivity

Infant perception has been one of the most exciting topics in perceptual development during recent years. This work has employed a variety of behavioral and physiological responses to index the fact that a stimulus has been registered by an S. The work has been reviewed in detail in Chapter 9 and it will be discussed here only insofar as it relates to developmental trends occurring after infancy.

The initial work in this area documented the fact that infants could make visual discriminations previously thought impossible. Fantz' pioneering work (Fantz, 1961b) is an example of this. He showed that infants preferred to look at complex patterned stimuli rather than homogeneous stimuli. Using this fact, he obtained a measure of the acuity of infants by pairing a homogeneous stimulus with a series of striped stimuli in which the width of stripe varied. It was reasoned that whenever a reliable preference was shown for the striped stimulus, then acuity must be at least high enough to resolve that width of stimulus. The results obtained were in good accord with measures using optokinetic nystagmus as an index of sensitivity (Fantz, Ordy, and Udelf, 1962; Gorman, Cogan, and Gellis, 1957; Dayton, Jones, Aiu, Rawson, Steel, and Rose, 1964). Such studies placed the acuity of infants of 0 to 1 month of age between 20/150 and 20/400 Snellen. In addition, acuity typically has been found to increase with age over the first few months of life.

The investigations of infant visual perception have been concerned with more than basic sensitivity and have tried to look at stimulus dimensions comprising the infants' visual world. The work on depth and shape has already been briefly described. Responsiveness to stimulus dimensions of complexity, amount of contour, and brightness have also been investigated. The interesting literature describing these results has made clear the necessity of obtaining coherent series of responses so as to be able to infer the stimulus dimension determining the response [see Bienen, Ames, and Moore (1966) on complexity,

Hershenson (1964) for brightness, and Karmel (1966) for contour].

Acuity continues to rise very rapidly through infancy and early childhood, and maximum acuity is usually attained by the age of 10 (Weymouth, 1963). This maximum is typically 20/20 to 20/15 Snellen and it refers to acuity of eyes corrected for focusing difficulties, that is, acuity based on the resolution capability of the retina.

However, one of the primary causes of poor vision in real-life is the inability of the viewer to focus the image properly. Recent work of Haynes, White, and Held (1965) suggests that neonates do not accommodate (change their lens focus) to the changing distance of stimuli. Their eyes have a fixed focus set for targets at approximately 8 inches. During the first several months of life infants improve in ability to accommodate to targets of different distances, and by the age of 4 months they adjust their accommodation quite precisely to the distance of the target.

It is common ophthalmological practice to regard the relaxed, unaccommodated eye as the standard from which to judge the refraction condition of the visual system. The relaxed or unaccommodated eye should focus on the retina parallel rays of light (i.e., rays of light coming from a distant target). This means the refraction of the light at the cornea and at the lens should result in the image being focused on the retina. For infants and young children the image is often focused behind the retina and they are termed hypermetropic. As the child grows older his eye becomes bigger and the distance from lens to retina increases more than is necessary for focusing the image on the retina. The image would now be focused in front of the retina (myopia) except that the lens and cornea become less refractive with age, helping to balance the change of focus due to increased size of the eye. The balance is not quite correct and there is a tendency for children to be hypermetropic and for adults to be myopic.

There is very little information on absolute thresholds for detection of light in children. The probable reason for this is the tedious procedure for obtaining such thresholds, involving long periods of dark adaptation followed by exacting judgments. There are a few data on contrast sensitivity. Doris and Cooper (1966) varied the brightness of white

stripes on a black background. They found that older infants (up to 69 days of age) showed optokinetic nystagmus with less bright stripes than did younger infants (down to 4 days of age). Unfortunately, the brightness of the background also varied and one cannot be certain whether the age change was a function of absolute or relative brightness. Pollack (1963) obtained an increase of contrast threshold as a function of age in children between 8 and 14 years. This is the only report of a decrease in sensitivity with children so young (see Eichorn, 1963). However, Pollack cites other evidence that sensitivity decreases as a function of age with older Ss. (This result is important for his theoretical position, which will be described subsequently.)

It is generally agreed that contrast sensitivity is closely related to contour formation. Hence it would be reasonable to expect developmental changes in other contour processes such as the type of masking described by Werner (1935): if a disc is presented briefly to an S, followed by a circumscribed ring, the disc may not be seen, the S reports that he has seen only a ring. On the other hand, if the disc alone is presented for the same amount of time, S has no trouble reporting it. Apparently the ring masks the perception of the disc. Parametric research has shown that the temporal duration of the disc and the interval between disc and ring are important determiners of degree of masking. Pollack (1965b) has investigated age changes in this phenomenon. He found that masking occurs with longer intervals between disc and ring in younger children (7 years) than in older children (10 years). Since masking has also been found to depend on figure-ground contrast, it was suggested that the effective age variable is the decrease in contrast sensitivity, which Pollack also observed.

Sensitivity to hue differences is also difficult to measure in young children because of the laborious psychophysical techniques necessary for precision. There were a number of early attempts to measure hue perception in infants, and these are reviewed in Munn (1965). The problem is an especially interesting one because languages divide the wavelength continuum differently. That is, some languages divide a given range of the visual wavelength continuum with many color

names, whereas other languages use only a few names. It would be a very interesting example of perceptual learning if preverbal children discriminate along the wavelength continuum differently from verbal children, and it might suggest an effect of language on perception. Before this question is asked it will be necessary to determine how preverbal children perceive hue. As Munn pointed out, it is necessary to rule out discrimination between hues on the basis of differential brightness. Investigators of hue perception in infants have mostly used preference measures, but they have also used the tendency for infants to track spots of one hue when moved against backgrounds of another hue. The brightness of the hues was equated in many of these studies by using values obtained from adults. As Munn points out this is a questionable procedure because the relative brightness of different colors may not be the same for infants and adults.

There has been relatively little work on hue discrimination with older children. Naviat (1965), using children from 3 to 10 years, observed increasing precision with age in matching pigmented tints. On the other hand, Pollack (1966), using more precise measurement techniques, found no age changes in hue discrimination with children between the ages of 7 and 12 years.

B. Auditory Sensitivity

The work on infant perception has included some interesting documentation of infant's auditory perception. For example, Steinschneider, Lipton, and Richmond (1966) found that the auditory threshold to sounds for 2- to 5-day-old infants was less than 70 db (relative to 0.0002 dyn/cm²). These investigators used changes in heart rate as a measure of infant sensitivity. It is important to note that the sensitivity of the infant is at least as good as observed here. It is quite possible that sounds are detected at lower intensities but not reflected in changes of heart rate. Bartoshuk (1964) was able to scale auditory stimuli using the same physiological response. He presented a series of sounds from 48 to 78 db (relative to 0.0002 dyn/cm²) to neonates 1 to 4 days old and measured their change in heart rate. He obtained a power function relating physiological response to physical intensity of the stimulus ($\Delta HR = I^n$ where

ΔHR = change in heart rate, I = intensity, and n is the exponent) The value of the exponent was found to be 0.53. Stevens (1961), using adults, had found n to be 0.6 for a power function relating judged magnitude of sound to intensity. The close agreement raises the interesting possibility that sound intensity is perceived similarly over a very wide age range.

Evidence for frequency discrimination, like evidence for hue discrimination, is difficult to obtain in pure form in infants. However, Leventhal and Lipsitt (1964) obtained data suggestive of a frequency discrimination when the frequency change was 200 to 1000 cps but not when the change was from 200 to 500 cps. They used such measures as changes in activity level and heart rate as indices of sensitivity. In addition, using cardiac rate measures, Bartoshuk (1962a) and Bridger (1961) provide some evidence for frequency discrimination in neonates between 100 and 1000 cps and 400 and 1000 cps respectively.

Auditory acuity in older children also has not been intensively studied. There is, however, at least one precise normative study. Eagles, Wishik, Doerfler, Melnick, and Levine (1963) used a large sample of school children between the ages of 5 and 14. Their data show an increasing absolute sensitivity to sound until 12 to 13 years. At the age of 14 there was a slight decrease in sensitivity. The maximum age difference, which was between 5 and 13 year olds at 250 cps, is only 6 or 7 db (relative to 0.0002 db). However, such large numbers of Ss were used that this difference was easily significant. The age differences are greatest at the lower frequencies, they decrease but are still present at the highest frequency tested, 8000 cps. The age differences are quite consistent, they occur independently in boys, girls, Negroes, and whites.

Recently McKee and Riley have investigated relational learning using auditory parameters (McKee and Riley, 1962, Riley and McKee, 1963, Riley, McKee, and Hadley, 1964). They utilized a transposition design to assess the degree to which children respond relationally to frequency and intensity of sound. The basic result is that more children (first to third graders) respond relationally after learning an intensity discrimination than after learning a frequency discrimination.

In transfer tests after frequency discrimination training neither children nor adults as groups respond consistently (absolutely or relationally). The amount of relational responding to frequency was increased for all ages if the interval between the training sounds was made smaller (Riley and McKee, 1963). However, a check with magnitude estimation scaling techniques indicated that the small size of the intervals between the training stimuli did not account for the greater amount of relational transposition for the intensity dimension. The investigators suggest the intriguing hypothesis that Stevens' (1961) distinction between prothetic and metathetic stimulus dimensions might apply to type of transposition. He has noted that psychophysical scales with different properties are obtained for stimulus dimensions such as intensity, which seem to depend primarily on amount of stimulation, and for dimensions like frequency, which appear to depend upon locus of stimulation. Intensity is a prothetic dimension and frequency metathetic. If such dimensions are typically mediated by different physiological mechanisms, our perception of them might also lead to relational or absolute discrimination learning.

C Sensitivity in the Lower Senses

Studies of tactual sensitivity in neonates have indicated that females are more sensitive to mild electric shock than males (Lipsitt and Levy, 1959). Stimulation of the neonates' feet with an aesthesiometer does not yield consistent sex differences, but stimulation of the abdomen with an air jet again produces greater sensitivity in females (Bell, 1964). Some previous observations had shown female adults to have higher tactual sensitivity than males. Ghent (1961b), in a study of children ages 5 to 11, found greater sensitivity in girls to stimulation of the center part of the upper arm. However, she found no higher sensitivity in girls to stimulation of the thumb, and over the age range studied there was a slight increase of sensitivity for boys but no consistent change for girls.

The response of children to simultaneous tactual stimulation has been studied by Fink and Bender (1953). When a child is stimulated simultaneously in two places on his body, for example, his cheek and hand, he may not detect one of the sources of stimula-

tion (extinction) or he may misperceive the locus of one of the sources (displacement) Fink and Bender found that the incidence of such errors decreases from 3 to 15 years. There is a marked practice effect, and even the older children make many errors in the early trials. Stimulation of the face seems to dominate other parts of the body, stimulation of the face rarely results in extinction, and stimulation of another part of the body often is displaced toward the face. The mechanism for this phenomenon is not clear. The authors try to relate it to Gestalt principles such as good closure, but their explanation is not very convincing. In their procedure the stimuli were applied by *E* simply touching *S*. The synchrony and intensity of stimulation cannot be very carefully controlled using such a method. This tactual extinction and displacement need to be studied with a better technology because they may be related to work on the ability to process more than one channel of information at a time (see Broadbent, 1958). Bekey (1967) has summarized a large number of technically elegant experiments with adults which appear to be related to these phenomena.

There has been some work with infants, for example, see Engen, Lipsitt, and Kaye (1963) on olfaction, but no other developmental investigations of basic sensitivity in other lower sense modalities. This is unfortunate since both theoretical and practical problems might well be illuminated with research, for example, on taste sensitivity. Taste buds are more widely distributed in the mouth of children than in adults, but there have been no systematic investigations to see if this wider distribution is correlated with greater sensitivity. Since gustatory stimuli are easy to mix, taste might be a convenient modality in which to do masking and detection experiments with children. In a practical vein, basic knowledge of children's taste sensitivity could be applied to preparation of food for children.

D. Laterality and Sensitivity

Differential sensitivity as a function of side of stimulation has been reported for vision, audition, and touch. The development of such sensory asymmetry has important implications for brain function and for perceptual learning.

A large amount of research has been con-

ducted on detection of stimuli presented to the right or left of a visual fixation point. A careful review of much of this work with adults can be found in Howard and Templeton (1966). If letters or words are flashed either on the right or the left but not both, those on the right are detected more easily. If letters or words are flashed simultaneously on the left and the right, those on the left are detected more easily. Two hypotheses have been advanced to account for these results, one has to do with differential localization of function in the brain and the other has to do with learned scanning tendencies. Mishkin and Forgays (1952), for example, concluded that training in reading establishes a more efficient neural organization in one visual hemisphere than in the other. Harcum (1964), on the other hand, posits the existence of a perceptual scan factor as well as a sensitivity factor. Only two developmental studies of this phenomenon have been conducted (Forgays, 1953, Dyer and Harcum, 1961). Forgays studied children from grades 1 through 12. He presented words either in the right or left visual field and found a gradually increasing advantage for words presented on the right. That this advantage is a function of experience or training is supported by other studies, which showed that for Hebrew readers words are recognized in the left visual field more easily (Mishkin and Forgays, 1952, Orbach, 1952). Dyer and Harcum also found a superiority of the right visual field for recognition of binary patterns. They attributed the result to a recency effect resulting from scanning left to right. The last element to be scanned is reported most accurately. If this interpretation is correct, Harcum's scan factor may be in reality a short-term memory phenomenon.

Greater auditory sensitivity on one side of the body than the other has been reported only under conditions in which the two ears are in competition. When different inputs are presented simultaneously to the two ears, the right ear has a higher accuracy for recognition of speech and the left ear for nonspeech sounds such as melodies (Kimura, 1963, 1964). In the only developmental study of this phenomenon (Kimura, 1963) the right ear advantage was greatest at the youngest age, 4 years. The lack of large differences at the older ages may have been attributable to

a ceiling effect since absolute performance levels were high. In any event there was not the expected developmental increase of lateral differentiation. The right ear advantage has been thought to be related to cortical lateralization of speech. There is considerable evidence (Penfield and Roberts, 1959; Zangwill, 1960; Lenneberg, 1967) that such lateralization, usually with the left hemisphere dominant, develops during childhood. Children who have lesions of the left hemisphere at early ages regain language facility completely, but adults with similar lesions remain permanently impaired. It may be that the perceptual advantage of the right ear is related to cortical dominance, but the relation must be a complex one. A possible mechanism for a lateral ear advantage (Shankweiler, 1966) would be stronger representation of the contralateral ear than the ipsilateral ear in the dominant hemisphere. Ongoing activity in the brain from this contralateral ear would block processing of input from the ipsilateral ear. Thus if the left hemisphere is responsible for processing speech, the right ear would have a competitive advantage from stronger cortical representation. Shankweiler summarizes some of the evidence for this hypothesis.

Observations of passive tactual thresholds by Weinstein and Seleson (1961) have revealed that sensitivity is greater in the non-dominant hand than in the dominant. Ghent (1961b), in a previously mentioned study, investigated whether this differential sensitivity developed with age between 5 and 11 years. In boys the differential sensitivity had developed by 11 years but in the girls it had not. For the 9- and 11-year-olds and a few of the children of other ages thresholds were determined for a section of the upper arm. The sensitivity of the nondominant arm was higher than that of the dominant arm at all ages, but the differences were not statistically significant.

There is a large literature concerned with the relation between lateral dominance and reading disability. In this case lateral dominance has referred to motor dominance, usually handedness. Although motor dominance is not the concern of the present chapter its relation to the perceptual aspects of reading makes consideration relevant. An early hypothesis was that left-handedness or ambidexterity reflected abnormal cortical lateralization

of function. This abnormal lateralization was thought somehow to affect adversely reading ability. Belmont and Birch (1965) adduce evidence to the effect that differences in lateral dominance between normal and retarded readers are found when the retarded readers are sampled from a clinical setting but not when they are obtained from a normal population. It is not clear what kinds of bias the selection from clinical populations introduces. At least clinical samples are not pure cases of reading difficulty.

One problem with studies relating lateral dominance to other functions is the rather arbitrary definition of dominance. Most investigators fail to distinguish between sensory and motor dominance. Furthermore, most of the motor dominance studies have used limb preference as the definition of dominance, but limb skillfulness might be a more meaningful way of defining such dominance. Finally, while dominance is often operationally defined by the hand used in some overt behavior such as ball throwing, a cortical lateral dominance is often inferred. Recently a technique has been developed (Wada and Rasmussen, 1960) which defines the cortical lateralization of speech production in a much more functional way. This involves infusion of sodium amytal into the arteries supplying one side or the other of the brain. A temporary aphasia results from infusing into the "speech dominant" side. The time appears ripe for a careful extensive study of dominance and laterality. This might include determination of laterality for a large number of functions in the same Ss to see whether functions are lateralized in clusters. Replicating such studies at different ages would further define related functions and would suggest fruitful hypotheses about brain function.

III. SENSORY INTERACTION³

A. Development of Body Image

To what extent is a person aware of the parts of his own body? Does he perceive their position, size, and state accurately? There is an extensive literature on this topic (see Schilder, 1950), but much of the evidence consists of clinical observations. These are

³ For a more extended treatment of some of these problems see Pick, Pick, and Klein (1967).

provocative, but they have not been investigated in normal populations. There is even very little clinical literature on the development of body image in children.

It is possible to distinguish two general types of questions about one's perception of his body. One has to do with being able to perceive parts of the body in relation to each other. The second has to do with perception of the body in relation to an external reference system. These capacities do not necessarily depend on a single mechanism. Schilder (1950), for example, describes the case of a patient who could indicate by appropriate marking of a diagram a position on a limb of the body that had been tactually stimulated, but the patient had no idea where the stimulated limb was when it was out of sight.

In investigations of body perception Ss are asked to make a response with respect to a stimulated part of the body. Often this means that S has to indicate a target part of his body with another bodily response. Any difficulty could be attributed to either perception of the target or the response indicator or both. Furthermore, Ss are often asked to *identify* stimulated parts of their body. This ability involves more than just discrimination of two parts of the body as different.

The simplest kind of appraisal of one's body perception is the determination of two-point thresholds at various places on the body surface. Dunford (1930) cites a study by Freedman which found a decrease in the two-point sensitivity (as measured by variability) for children up to the age of 12, then an increase. However, a study by Wundt is cited to the effect that children have a smaller space threshold than adults. This question is still unresolved.

At a somewhat more complex level of body perception, Ss can be asked to indicate a point on their body which *E* had stimulated. Dunford (1930) and Renshaw (1930) both reported developmental studies in which Ss were asked to localize points on their hand or arm that had been tactually stimulated by *E*. Localization was accomplished by pointing with a stylus held in the other hand. The two studies were consistent in finding that precision was greater in younger children than adults. Renshaw suggested that the decrease in precision with age might be due to a shift from tactual-kinesthetic orientation to visual

orientation. If this were the case, older children and adults might be better at localizing with a visual response while they were becoming worse at localizing with a tactual-kinesthetic response. A visual localizing procedure might involve touching S and having him open his eyes and report graphical coordinates of the point stimulated. Renshaw found preliminary support for this prediction in the same study and subsequently verified it (Renshaw and Wherry, 1931). Visual localization becomes more accurate with age, especially between 13 and 14 years, while tactual-kinesthetic localization as defined in this task becomes worse.

This interesting, unusual result of decreasing accuracy in performance with age should be replicated since the age trends found by both Dunford and Renshaw are rather irregular and are based on relatively few Ss. Another study (Renshaw, Wherry, and Newlin, 1930) provides evidence that the performance of well practiced Ss does not decay with age. The performance of congenitally blind Ss improved with age. That precision may generally be a function of amount of use is suggested by the fact that both Dunford and Renshaw found marked practice effects at all ages.

Clinical observations have indicated that there may be difficulties in discriminating between structurally similar body parts such as the same member on opposite sides of the body or adjacent fingers. Some of these observations have been the subject of developmental investigation. Kinsbourne and Warrington (1963) report a study of children between the ages of 4½ and 7½ involving a number of finger differentiation tests. In one test blindfolded children were stimulated simultaneously on two parts of their fingers. They had to report whether the points were on the same finger or on two different ones. In a second test *E* touched two different fingers and S was required to report how many fingers there were between the two. Performance in the tests improved from below 40% correct at age 4½ to close to 100% correct by age 7½. Unfortunately, the results are presented only in terms of percent correct and are not broken down into different types of errors.

Finger identification has been studied in a series of investigations by Benton, many of

which are summarized in one source (Benton, 1959). Using a 50-item test battery Benton conducted a normative study of 150 school children between the ages of 6 and 9. The test items were of the nature of pointing to or naming individual fingers on oral command with eyes open or closed, or indicating which finger had been touched by *E*. Results indicate a marked improvement as a function of age. Since it is an identification experiment, it is not clear how much of the change represents perceptual improvement. The pattern of errors, however, is interesting. The order of number of errors from most to least is third finger, second finger, pointer finger, little finger, and thumb. The differential pattern of errors may well be a failure of discrimination rather than identification. The correlation between errors of the right and left hand was relatively high (.54). In a study of adults Elithorn, Piecy, and Crossky (1953) found that the second finger, rather than the third finger, was least accurately identified. Whether the difference between their and Benton's study represents a real developmental change or whether it is due to a somewhat more complicated procedure in their study is not clear. Benton (1955) found poorer performance on the same test battery in a group of retardates matched with normals on MA. This confirmed a similar finding of Werner and Garrison (1942).

So far the developmental studies of body image have dealt with precision of perception, but there are two studies relevant to the qualitative nature of the body image. McKinney (1964), in an imaginative study, asked children ranging in age from 4 to 8 to indicate which finger he touched. The interesting experimental condition was one in which the child had to turn his hand over before responding. The younger children made a great many errors in which they responded to the original spatial position rather than to the correct finger. This was not due to motor interference or distraction since the young children performed quite well in a condition in which they turned their hand over and back again before responding. McKinney suggests that the younger children are responding in terms of a visual image of the hand. He supported this hypothesis by showing that congenitally blind children did not make such errors.

The second study (Simmel, 1966) of qualitative aspects of the body image investigates the relation between age of amputation of a limb and occurrence of a phantom limb. It was found that if the amputation occurs very early a phantom limb is less likely to be experienced. For example, only 20 to 25% of Ss whose amputations occurred before the age of 4 reported phantoms, whereas 61 to 100% of Ss whose amputations occurred after the age of 4 reported phantoms. There was some confounding between age of amputation and time elapsed since amputation but probably not enough to account for the marked relationship.

The clinically observed difficulty in discriminating the right from left side of the body is not found in normative studies even in young children. However, the identification of the right and left parts of the body is an entirely different matter. There are a number of studies that show this ability is poorer in young children and improves steadily with age (Swanson and Benton, 1955, Benton, 1959, Belmont and Buch, 1963 and 1965). These studies evaluate right-left awareness by using such items as *raise your right hand*, and *point to your left ear with your right hand*. In Benton's (1959) study the test battery is most elaborate and involves performing the right-left identification tasks with eyes open and closed, with active movement and passive movement, and on pictures of other persons. Again there may be a perceptual and an identification component to the child's difficulty. The perceptual component is probably related to children's difficulty in discriminating right and left mirror images from each other (see Section IIIB on orientation). In addition, learning proper identification of right and left may be hampered by the fact that right and left do not have consistent meaning relative to the child. These terms are also used to label other people's position and are often reversed with respect to the child's orientation.

One could perhaps use a reaction time procedure for assessing the perceptual discriminative aspects of right-left perception. For example, the reaction times for same-different judgments could be compared for simultaneous stimulation of different parts on the same and opposite side of the body.

There appear to be no systematic studies

of the accuracy with which children perceive their own body dimensions. However, one study does touch on this problem. Smith and Smith's (1966) factor analytic study found two tasks involving estimation of arm length which yielded a perceptual factor. Unfortunately, the actual values of the estimates were not reported and two other tests of arm length estimation were not included in this factor.

One final aspect of body perception concerns the locus from which *S* perceives his own body. Natsoulas and Dubanoski (1964) investigated this problem with adults by tracing ambiguous (reversible) letters on the forehead, sides, and back of head. They asked *S* to report the letter they experienced. Thus if *E* traced a "b" on the forehead, *S* might perceive this as a "b" or a "d," depending on where his locus of perception was. They found that *S* tends to report as if he were standing behind the head and looking forward. Thus a "b" on the forehead from *E*'s point of view is perceived as a "d," whereas a "b" on the back of the head is perceived as a "b." Recently Dubanoski (1965) and Podell (1966) have replicated this procedure with children. In general they both found the same pattern of results for children from 6 to 16 (Dubanoski) and from 3½ to 11 (Podell). In some conditions both these investigators found greater proportions of children than adults responding as if they were standing in front of the head and looking back. Dubanoski further showed that older children could, if required, make judgments as if viewing from *E*'s point of view, whereas younger children could not. He related this to Piaget's observations that older children are better able to imagine relative orientations from different points of view.

B. Orientation

The perception of orientation of stimuli will be considered as a problem of sensory interaction since in some cases more than one modality is involved. For example, judgments of orientation often refer the visual orientation of a stimulus to the direction of gravity. Sometimes, of course, only one modality is involved, for example, when one visual stimulus is compared with another.

Howard and Templeton (1966) have made a comprehensive analysis of the mean-

ing of various questions about orientation. Here the concern will be with the developmental aspects of such questions only. It has long been known that young children tend to confuse a visual shape with rotations and mirror images of itself. Recent documentation of this fact can be found in Gibson, Gibson, Pick, and Ossei (1962), who reported that 4-year-olds made such confusions in approximately 45% of the relevant cases. In that study a standard shape was paired with 45°, 90°, and 180° rotations and right-left and up-down mirror images. Confusion errors between all of these transformations and the standard shapes decreased with age. However, the mirror images continued to produce more errors than the other rotations.

Paradoxical results have been reported by Ghent (1961a), who asked children between the ages of 4 and 8 to indicate which of two shapes (up-down mirror images of each other) was upside down. Four-year-old children showed remarkable intersubject consistency in their selections. The difference in results between Gibson et al. and Ghent might be due to the difference in the particular forms used or it might be due to the different question asked. In the study by Gibson et al. the *Ss* were asked in essence to make same-different judgments, whereas Ghent asked her *Ss* directly to identify an orientation. The questions asked might have produced the divergent results by directing the children's attention to different aspects of the stimuli. Ghent has also shown that the orientation of figures makes a difference in recognition tasks (Ghent, 1960; Ghent and Bernstein, 1961). Children were asked to identify forms shown tachistoscopically. Forms which were right-side up were identified more accurately than those which were upside down. This difference occurred both with forms representing real objects and with nonsense forms which previously had been found to have orientations that were reliably judged as right side up and upside down. The difference in accuracy between the two orientations decreased with age from 3 to 7 in the case of realistic forms. It seems quite clear that the observation often made that children look at pictures upside down does not mean that they are insensitive to differences in orientation.

Ghent has proposed a scanning mechanism

to account for these results (Ghent, 1961a). She hypothesizes that children tend to scan from top to bottom of a form. She further noted that many of the forms that were reliably identified as upside down had "focal points" at the bottom. Her suggestion is that the focal point attracts the initial attention of the child. When this is at the top, it is congruent with the normal scanning tendency and the form is judged as right side up. When the focal point is at the bottom, the child's attention is attracted to it and he has to scan from bottom to top. This is counter to his normal scanning tendency and the shape is judged as upside down. The scanning may well be implicit since Ghent herself has demonstrated the preceding results with tachistoscopic presentation at speeds too great for actual eye movements to occur.

Ghent's scanning hypothesis has been investigated in two studies. Wohlwill and Wiener (1964) reasoned that if Ghent's scanning hypothesis were correct, then orientation would be better discriminated in stimuli that had high directionality, internal detail, or were open in comparison with stimuli that had low directionality, no internal detail, or were closed. It was thought that the presence of these properties would facilitate scanning from a focal point. Ability to discriminate orientation was tested in 4-year-old children using a matching-to-sample technique. Only the variable of directionality made a significant difference. Although this variable lacks precise definition it is obviously most relevant to the scanning hypothesis. Ghent herself (Braine, 1965) did a study in which she asked 3- to 5-year-old children to identify a tachistoscopically exposed stimulus from an array of similar stimuli. The stimuli were designed so they had focal points at one end and distinguishing features at the other end. The hypothesis of the study was that young children would recognize the forms more rapidly when they had the focal point at the top and the distinguishing features at the bottom since this arrangement would be congruent with their natural scanning tendency. The younger children recognized the right side up figures more accurately than the upside down, but the results were reversed for the older children. There is some other evidence (Ghent, 1963) that older children and adults scan from top to bottom independently

of the specific stimulus. Thus the general interpretation of the results is that stimulus factors and scanning tendencies both operate for younger children, but only the scanning tendency is important for older children. They start at the top of the figure and if that is where the distinguishing feature is they can use it immediately.

One difficulty with the Ghent hypothesis is that there are apparent exceptions. In some cases stimuli with obvious focal points do not obey the rules. However, in many of these cases the form has a representative function and the judgment of orientation is made in terms of the object that is represented. In other cases there is no reasonable focal point, nevertheless, consistent judgments of orientation are made. This leads to a second difficulty for the Ghent hypothesis, which is the lack of a precise definition of focal point. In many cases observers would agree that a focal point is present. In some cases, however, observer agreement could not be obtained. In summary, it is quite likely that several factors influence judgments of orientation but Ghent has no doubt identified an important one.

There has been some investigation of the generality of the orientation phenomenon. Antonovsky and Ghent (1964) found similar identifications of orientation in Iranian children. Pick, Klem, and Pick (1967) found similar identifications on another set of nonsense forms, but the consistent identification disappeared when the task was performed tactually without vision. Neither were there consistent identifications by totally blind Ss. However, partially sighted Ss did show consistent tactual identifications which were similar to the visual identifications. Goldstein has investigated the effect of change of vertical orientation on recognition and learning of photographs of faces. Brooks and Goldstein (1963), studying children between 3 and 14 years, found that older children are relatively better at recognizing inverted photographs of their peers than are younger children. On the other hand, when the task was learning to associate a letter with a facial photograph, children performed relatively better than adults with inverted photographs (Goldstein, 1965). The paradox of these two sets of results has not yet been resolved.

As previously noted, confusions of right and left mirror images with each other are

also quite common among children. In the study of Gibson, Gibson, Pick, and Ossei (1962) the level of errors for up-down mirror images was approximately the same as that for right-left mirror images. It has more often been found, however, that right-left mirror images are more difficult. For example, Davidson (1935) found quite consistently with the letters *b*, *d*, *p*, and *q* that the right-left mirror images were confused more than the up-down. Further, Rudel and Teuber (1963) found that it is more difficult to learn to discriminate between right-left mirror images than between up-down mirror images. One possibility suggested for the difference in difficulty between these transformations is an interaction between the type of transformation and the direction of their alignment. Both transformations are usually presented in a horizontal alignment and this may make comparison of the left-right mirror images more difficult. Sekuler and Rosenblith (1964) and Huttenlocher (1967) have tested such a hypothesis. Sekuler and Rosenblith found a marked interaction, as predicted, in a situation involving same-different judgments. There were very few confusions of up-down mirror images when they were horizontally aligned, but a large number when they were vertically aligned. On the other hand, there were very few confusions of right-left mirror images when they were vertically aligned and a large number when they were horizontally aligned. Huttenlocher found similar results in a discrimination learning situation. Learning to discriminate between right-left mirror images was relatively more difficult when they were horizontally aligned than when they were vertically aligned. The converse was true with the up-down mirror images, although the magnitude of the difference was rather small.

Why should there be an interaction of this type? A scanning hypothesis might be invoked. Suppose *S* scanned repeatedly across a pair of stimuli in the direction of their alignment, as in a TV scanner, registering only the number of elements present on each scan. Then left-right mirror images would register identically in horizontal alignment, and up-down mirror images would register identically in vertical alignment. Discrimination based on such registration would seem to handle most of the existing results as far

as the difference between left-right and up-down mirror images are concerned. For example, in the Gibson, Gibson, Pick, and Ossei study where the usual difference was not found, the situation did not involve consistent horizontal or vertical alignments of the stimuli. The model is, in essence, an extension of one suggested by Sutherland (1961) to account for shape discrimination performance in the octopus.

C. Intermodal Relations

The theoretical point of view most directly concerned with intermodal interaction is the sensory-tonic field theory developed by Heinz Weiner and Seymour Wapner (Weiner and Wapner, 1949). This point of view has been integrated with Werner's developmental theory (Wapner and Weiner, 1957). The basic assertion is that perceptual experience is a function of the relation between stimulation and the organismic state. In this theory stimulation and body tonus or state can be considered to be distributed symmetrically or asymmetrically with respect to body axes. When stimulation and body tonus are congruent, as when they are both symmetrical, their relation is considered to be stable. When they are noncongruent, as when body tonus is asymmetric and stimulation symmetric, their relation is considered to be unstable. When unstable, there is a change in the state of the organism which is reflected in a change in perception. The paradigmatic problem is perception of verticality. The *Ss* are asked to judge whether a rod is aligned vertically or not. If the task is presented when *S*'s body is upright and tonus is symmetrically distributed, the judgment is made accurately. If the body is tilted and tonus is asymmetrically distributed, there is an unstable relation leading in some cases to incorrect judgment of the verticality of the rod. Asymmetric stimulation may be applied by such means as an extraneous sound to one side of the head, or by a nonsymmetric starting position of the rod to be judged. It is Werner's view that development proceeds by increasing differentiation and hierarchic integration. One implication of this view is that there is increasing differentiation of self from object as a function of age. It is then predicted that the effects of extraneous stimulation will decrease as a function of age.

Wapner and Werner (1957) report an interesting factorial experiment in which they examined the effect of body tilt and starting position of a rod on judgments of verticality. Using children ranging in age from 6 to 19 they found that the youngest Ss tended to report the rod as vertical when it was tilted slightly (0 to 4°) in the direction of the body tilt. The oldest Ss reported it as vertical when it was tilted in the direction opposite to the body. Starting position biases the Ss toward judging the rod as vertical when it is tilted in the same direction as its initial position. This effect is present at all ages but its magnitude decreases with age. The decrease is consonant with the hypothesized differentiation of self from object. The change in the effect of body tilt with age eventually leads to overcompensation in adults; they judge the rod as tilted away from the direction of their body tilt. Similar results of decreasing effect with age were shown by these investigators in two other situations. In one, the task was localizing the median plane when a figure in the visual field was asymmetrically placed. In the other, the task was maintaining head strain when illumination of the visual field was asymmetric.

The development of adaptation to visual distortion has been studied within the framework of sensory-tonic theory. Giannitrapani (1958) reasoned that if organism and environment are less differentiated in children, these children would feel greater impact of sensory distortion. This in turn would result in greater adaptation or adjustment to the visual distortion. Giannitrapani studied adaptation to visual magnification and tilt and to kinesthetic tilt, and he found the predicted trends. There were also some sex differences in the visual and kinesthetic tilt situations. Giannitrapani's analysis implies that the initial reaction of the children to the distortion would be greater than that of adults. An investigation by Klein (1966) measured the initial response to three situations in which visual and proprioceptive information were put into conflict by means of visual distortion. The task was to respond to the proprioceptive information, not the visual. The response of Ss at all ages was biased by the visual information, but there was a trend toward decreasing visual bias as a function of age.

The sensory-tonic field theory has instigated

a great deal of interesting work on the problem of sensory interaction. It has been criticized (see Howard and Templeton, 1966) and probably fairly for making an artificial distinction between organism and stimulation. The distinction apparently intended is often that between exteroceptive and interoceptive stimulation. Furthermore, it is not always clear how the stimulation and tonus are asymmetric. For example, Howard and Templeton argue in one case that the tonus in body tilt is distributed on the side opposite that indicated by Wapner and Werner. The hypothesis of greater differentiation with increasing age is applied in this framework mainly to the concepts of self and environment, but this seems unnecessarily restrictive.

IV. PERCEPTION AND INDIVIDUAL DIFFERENCES

A. Perception and Intelligence

The classical empiricist position emphasizing the effects of experience on perception implies a relationship between perception and intelligence. Consider perceptual constancy as a model: it might be expected that degree of constancy would improve with increasing intelligence since constancy may involve integrating a number of different cues in order to make an accurate judgment. For size constancy, for example, the size of the retinal image is thought to be registered in relation to the distance of the object to yield an accurate perception. The evidence does not support this line of reasoning. There are a number of studies which show that degree of size constancy increases with chronological age but not with intelligence. Zeigler and Leibowitz (1957), for example, asked 13-year-old boys and men to estimate the size of rods placed at distances ranging from 10 to 100 feet. The task required that they select a comparison rod of the same size from a group of stimuli 5 feet away. The children and adults showed a similar high degree of constancy for near stimuli. As the distance increased the adults continued to show a high level of constancy, whereas the children showed progressively less constancy. On the other hand, Leibowitz (1961), in a very similar situation using adult college students and adult retardates with an MA of 8.7 years, found equal and high constancy at all distances for both groups.

One of the most instructive studies is that of Jenkin and Feallock (1960). These investigators used approximately matched CA and MA controls in a size constancy study similar in principle to the studies of Leibowitz. A group of retarded children with mean CA of 15 years, 10 months and mean MA of 8 years, 2 months was compared with normal children with mean CA 8 years, 3 months and with normal children of mean CA 13 years, 7 months. An additional group of normal adults, mean CA 26 years, 6 months, was also tested. Again constancy increased as a function of chronological age but not of mental age. The retardates showed approximately the same degree of constancy as the 13-year-old normals, more than the 8-year-old normal Ss, and less than the adults.

The Gestalt position is another theoretical orientation from which relatively explicit predictions have been made for retarded Ss. With some roots in Lewin's concept of rigidity (Lewin, 1935) but based primarily on Kohler's theory of brain physiology (Kohler and Wallach, 1944), predictions have been made that figural aftereffects should be more difficult to establish in retardates than in normals. It is reasoned that the hypothesized satiation which is considered responsible for figural aftereffects occurs more slowly in retardates. This prediction has been confirmed in a number of studies (e.g., Spitz and Blackham, 1959, and Spivack and Levine, 1959). Spivack and Levine found a correlation of about .50 between susceptibility to figural aftereffects and intelligence in retarded children, but a zero correlation in normal children. Gestalt physiology notwithstanding, the same predictions might have been made on the basis of the task requirements. The induction of figural aftereffects requires prolonged visual fixation, a task that may be more difficult for retardates than for normals. The satiation model has also been used to predict a lower reversal rate for reversible figures by retardates. Such a prediction has not been consistently confirmed (see Spivack and Levine, 1959). Comprehensive general reviews by Kodman, by Spitz, and by Spivack of research on sensory and perceptual processes in retarded Ss are available in Ellis (1963).

Pollack has pursued a promising approach to the relation between intelligence and perception (Jenkin and Pollack, 1966; Pollack,

1969). He has observed, following Piaget, that there are two types of illusion. One type decreases in magnitude with increasing age, and a second type increases as a function of age. For Piaget the basis for changes in both these types of illusion are changes in the way a child scans. Pollack suggests that two different mechanisms are implicated. He refers the decrease in the first type of illusion to physiological processes independent of intelligence. For example, the Muller-Lyer illusion decreases with age and with increasing foveal pigmentation (see Section IA on depth perception). It also decreases with decreasing figure-ground contrast of the elements of the illusion (Pollack, 1963). Pollack found that contrast threshold increases in age from 8 through 12 and suggests that this might account for the decrease in the Muller-Lyer illusion. As predicted, the magnitude of the illusion was significantly correlated with contrast threshold but not with intelligence.

On the other hand, Pollack suggests that some of the illusions which increase in magnitude with age, such as the Usnadze illusion, are related to intelligence. The Usnadze effect is similar to a figural aftereffect except that the exposure times are shorter. If two concentric circles are presented successively, the inner after the outer circle, the inner circle appears to be smaller than it really is. This illusion increases with age, as do figural aftereffects (Piaget and Lambercier, 1944; Pollack, 1964). In the Delboeuf illusion, which is elicited by two concentric circles presented simultaneously, the inner one appears larger than it really is. The magnitude of this illusion decreases with age (Piaget, Lambercier, Boesch, and Albertini, 1942). Thus changing the presentation of an illusion from successive to simultaneous changes its direction and its relation with age. Pollack (1964) has been able to demonstrate an analogous result with the Muller-Lyer illusion. He used a modified form of the illusion and presented the elements successively. The direction of the illusion was reversed: the arrow-tail portion was judged shorter, and the magnitude of this reversed illusion increased with age. Furthermore, in this successive form of the illusion the magnitude of illusion is highly correlated with IQ. Within each age group from 8 to 11 years these correlations varied from .73 to .93.

The hypothesis proposed by Pollack (1966)

Table 1 Development of Susceptibility to Illusions

Table adapted from Wohlwill (1960). We are indebted to Dr. Cynthia Gliner for bringing it up to date.

^a Illusion cited by Wohlwill (1960) and study taken from his references.

^b In each illustration of illusion comparison is to be made between segments marked *a* and *b*. For the size-weight illusion the larger of two equal weights is perceived as lighter. For the Poggendorf illusion the two segments of the diagonal are typically seen as nonlinear.

is that phenomena involving temporal integration are related to intellectual ability. This, of course, must be investigated empirically and Pollack is doing so. It leads one to speculate whether intermodal transfer or integration might also be related to intellectual capacity. Such an extension must be complex, and it leads to a paradox. For example, the size-weight illusion must depend on confusing weight and size information, that is, the senses interact, but inappropriately. It is the case that the magnitude of size-weight illusion is less in retardates than in normals (Spivack, 1963) and this illusion does not increase with age. Table 1, adapted from Wohlwill (1960), lists a number of perceptual illusions that have been studied developmentally and indicates the age trends if any were found.

B. Perception in Cognition and Personality

A problem which has received considerable attention during the last few years is that of consistency and generality of cognitive and personality characteristics in perception and perceptual development. Witkin (Witkin, 1949; Witkin, Lewis, Hertzman, Machover, Meissner, and Wapner, 1954; Witkin, Dyk, Fatterson, Goodenough, and Karp, 1962) and more recently Kagan (1965a and 1965b, 1966; Kagan, Moss, and Sigel, 1963; Kagan and Rosman, 1964; Kagan, Rosman, Day, Albert, and Phillips, 1964) and Gardner (Gardner, Holzman, Klein, Linton, and Spence, 1959; Gardner, Jackson, and Messick, 1960; Gardner and Schoen, 1962) have conducted extensive investigations of individual preferences or predispositions in perceptual functioning. These are presumed to account for qualitative differences in perceptual functioning when stimulus conditions and subject ability are held constant.

Kagan's procedures yield correlation data from many measures on early and middle elementary school children. Among these measures are (1) response times in perception tasks in which alternative solutions are available, (2) indices of the tendency to analyze visual stimuli into components, (3) errors in perceptual discrimination tasks, and (4) preferences for analytic groupings in a concept sorting task. Kagan concludes that his investigations reveal "two basic cognitive dispositions that appear to have generality and stability: the tendency to analyze visual arrays

and the tendency to reflect upon alternative-solution hypotheses" (Kagan et al., 1964, p. 36). These dispositions are postulated to be independent of each other and of verbal ability and "each of these dispositions contributes considerable variance to the production of the more complex cognitive products of analytic concepts and recognition errors on tasks requiring complex perceptual discriminations" (Kagan et al., 1964, p. 36). Thus measures (1) and (2) above are predictor variables, and measures (3) and (4) above are criterion variables.

The evidence with respect to Kagan's hypotheses is somewhat equivocal (see Kagan, 1966, Tables pp. 511-512). The measures of these dispositions toward visual analysis and reflection do appear to be independent of each other and are also unrelated to WISC verbal skill measures. However, the intrasubject consistency of these measures varies (see Kagan et al., 1964, Tables p. 24). The test-retest correlations for the visual analysis measure are -0.05 , $+0.49$, $+0.20$, and $+0.05$ for different subject groups, those for one of the response time measures are higher: $+0.54$, $+0.74$, $+0.71$ and $+0.51$. The intra-individual consistency or the criterion variables is also reasonably high: r s of $+0.56$, $+0.60$, $+0.84$, $+0.44$, for perceptual recognition errors and $+0.70$, $+0.43$, and $+0.47$ for the measure of analytic sorting.

The various measures of the reflection tendency: response times are not highly related to each other, slightly less than half of the 24 correlations between response times on different tasks are $+0.40$ or greater (see Kagan, 1966, Tables pp. 511-512). Thus it is not clear that these response time measures are tapping a general dimension of reflection-impulsivity.

Given the moderate degree of stability and generality of the measures of reflection-impulsivity and visual analysis, it would be surprising if these variables accounted for most of the variance in the criterion tasks. Indeed, this is the case (Kagan, 1966, Tables pp. 511-512): correlations between reflection measures (response times) and errors on the same perceptual recognition task range from -0.11 to -0.67 with a median r of about -0.50 , correlations between reflection measures in one perceptual task and perceptual recognition errors in a second task range from $+0.31$ to

— 58 with a median r of about — 33. Correlations between reflection measures and analytic sorting, the other criterion variable, range from — 05 to + 47 with a median r of about + 15. Visual analysis, the second predictor variable, has correlations with perceptual recognition errors ranging from + 03 to — 41 with a median r of about — 22, visual analysis is related to analytic sorting as evidenced by r s of — 13, + 44, + 45, and + 10. Thus the independent predictor variables, reflection and visual analysis, account for only small amounts of the variance of the criterion variables of recognition errors and analytic sorting.

In summary, the evidence does not clearly support the hypothesis that the two dispositions toward visual analysis and reflection contribute substantially to production of analytic concepts and perceptual recognition errors. Particularly the measure of visual analysis shows less than desirable reliability. Furthermore, the several reflection measures show only moderate relationship to one another. Finally, these measures are not highly related to the criterion measures of analytic concepts and perceptual recognition errors.

The hypothesis that individual tendencies or "styles" of analyzing and responding to stimuli should have a broad effect on perceptual functioning is an appealing one and it may be that a different research strategy might provide stronger support for it. For example, Lee, Kagan, and Rabson (1963) conducted an experiment using as Ss boys who represented the extreme ends of a distribution of scores for production of analytic concepts in the sorting task. These two groups differed in the ease with which they acquired concepts based on similar elements of complex stimuli in a learning task. In other words, Ss who spontaneously grouped stimuli on the basis of certain characteristics also found it easy to learn concepts based on the same type of characteristics. Perhaps this strategy of utilizing Ss manifesting clear differences on some behavior dimension and then observing their performance in tasks whose requirements are carefully analyzed may reveal stable and general individual differences in perceptual functioning. A step-by-step analysis of subject characteristics, task requirements, and relationships between tasks may prove more fruitful than large correlational studies involving

performance on widely differing and often unrelated tasks.

Witkin's program of research has been extremely ambitious and prolific. His goal has been to relate personality characteristics to perceptual functioning. Degree of dependence on the visual field has been studied using a variety of perceptual measures. Two of the measures used to define this dimension require S to establish the upright in the presence of a distorting visual frame of reference. One, a rod-and-frame task, requires S, while in the dark, to adjust a luminous rod to the true upright when both it and a surrounding luminous frame are tilted. Another task requires S to adjust a chair in which he is seated to upright when both the chair and the room in which it is located are tilted. The extent to which the S ignores the visual field (either the frame or the room) as a frame of reference and is able to set the rod or his own chair close to the true upright is a measure of his field dependence or independence. If he is dependent on the field, he would tend to set the rod or chair in alignment with the field. However, the measure recorded is the deviation from true upright in degrees (Witkin et al., 1954, p. 33). This measure does not take into account direction of deviation. One investigator (Gruen, 1955, 1957) observed many Ss who overcompensated in these tasks. Although overcompensation and undercompensation may both reflect an influence of the visual field, their underlying mechanisms may be quite different. Perhaps direction of deviation should be taken into account in these tasks.

A third task used as an index of relative degree of field dependence or independence is an embedded figures task in which subjects are asked to locate a simple figure in a more complex pattern. For this task the measure recorded is the amount of time elapsed before a correct solution is reached.

The developmental trends in all three tasks are quite consistent and similar. Between the ages of 8 and about 17 years there is a decrease in relative field dependency. That is, older Ss take less time to locate the embedded figures and they adjust the rod or chair closer to the true upright than do younger Ss. Thus field independence is considered a more advanced level of development than field dependence. There are also consistent sex dif-

ferences with boys and men showing a greater degree of field independence than girls and women. It is interesting to note that Witkin has identified a response dimension which varies with age, and he uses it to interpret individual differences even in adults as reflecting different degrees of psychological development. However, he has stopped short of interpreting the lesser field independence of women as reflecting a lower level of psychological development!

The relationship among the measures for the various tasks is moderate. The median correlation coefficients between the rod-and-frame and embedded figures tasks of different groups are .32 for women and .44 for men. Those between the chair adjustment and rod-and-frame task are .37 for women and .42 for men. The median coefficients between the chair adjustment and embedded figure tasks are about .36 for women and about .33 for men (Witkin et al., 1954, Tables p. 144).

The personality variables hypothesized to be related to mode of perceptual functioning have been measured in a variety of tasks, for example, Rorschach, TAT, figure-drawing tests, and clinical interviews. An evaluation of the validity of these measures is beyond the scope of this chapter, but Postman (1955) and Zigler (1963) in reviewing Witkin's work have argued that this problem has not been adequately dealt with. It would seem to be an important problem since the underlying thesis of Witkin's work is that the personality variables determine the individual differences in perception. In the present context, then, it is relevant to review the degree of relationship between the perceptual and personality measures.

For adult groups of Ss, median correlations between perceptual measures and interview variables (e.g., ratings of degree of self-awareness, repression of hostility, self-esteem) range from .33 to .54. Median correlations between the perceptual measures and Rorschach measures (e.g., scores for Whole, Popular, Color, for *m* responses) range from .22 to .41. Median correlations between perceptual measures and figure drawing scores (e.g., lack of body confidence, lack of drive) range from .45 to .63, and the median correlations with TAT scores (e.g., lack of self-assertiveness, unfavorable outcome) range from about 0 to .45 (Witkin et al., 1954,

Tables pp. 191-192, 218, 246, 274). Thus the relationships between perceptual measures and personality measures can be described as low to moderate. It has been argued (see Postman, 1955, Zigler, 1963, Gruen, 1957) that there are some methodological problems with these procedures some of which would inflate the correlation coefficients, for example the specific manipulations employed in obtaining the personality scores, familiarity by *E* with the hypothesis being tested in situations where scoring is quite subjective, and unreliability of scoring the personality measures.

It is difficult to assess the strength of the suggested personality-perception relationships in children since most of the studies do not present correlation coefficients. However, reference is made in one report (Witkin et al., 1964, p. 190) to correlations obtained with children between perceptual measures and figure drawing. These correlations range from .44 to .76. Zigler (1963) has suggested that such relationships may be accounted for by factors common to these measures and standard intelligence measures. This possibility has not been explored fully but did receive some support from Gruen (1957). He found lower intercorrelations than Witkin and different patterns of intercorrelation among the perceptual and personality measures separately, but he found personality-perception correlations of the same magnitude as Witkin. Furthermore, a factor analytic study (Goodenough and Karp, 1961) found significant relationships between the perception measures and performance on several subtests of the WISC.

In summary, it can be said that much research has been stimulated by Witkin's ideas. Many of the studies support the relationships hypothesized by him (Dyk and Witkin, 1965, Witkin, 1950, 1964, Witkin et al., 1966, Witkin and Wapner, 1950), but there are many that do not (Dana and Goocher, 1959, 1960, Vaught and Ellinger, 1966, Vaught and Auguston, 1967, Gruen, 1957). The lack of consensus among the studies may be due to the vagueness of the basic concepts and consequent difficulty in investigation or it may be that the relationships are not as decisive as Witkin suggests. A more general hypothesis is that Ss respond to these tasks differently and neither the perception nor the person-

ity measures reflect unitary dimensions. In other words, the individual differences may reside not in the ways Ss perceive the world, but in terms of their interpretations of the task presented.

A third extensive program of investigation concerned with individual differences is that of Gardner (Gardner et al., 1959, 1960, Gardner and Schoen, 1962, Gardner and Long, 1962, Holzman and Klein, 1954). The particular individual tendencies which these investigators have explored are termed cognitive controls. These controls are viewed as structures or organizational tendencies that mediate an individual's perceptual cognitive and personality functioning. Examples of some controls are tendencies toward constricting or flexibility and toward leveling or sharpening. Each of several controls has been defined in terms of specific tasks, and factor analytic techniques have been employed to investigate the nature and generality of the hypothesized controls. The controls are assumed to be dimensions rather than dichotomies for categorization of behavioral tendencies.

The bulk of this careful and systematic investigation has been conducted with adult samples. The stability of the measures of cognitive controls appears fairly high. 3-year test-retest data on one sample yielded correlations ranging from .36 to .75 with a median r of about .60 (Gardner and Long, 1960). Unfortunately, little work with children has apparently been reported. However, Gardner suggests that studies with children of the development of stable cognitive control patterns are important parts of the general investigation (Gardner et al., 1959, 1960) and has indicated that an extensive investigation of this type is underway (Gardner, 1964). One study with children by the Gardner group is a cross-cultural study in which Mexican and U.S. children of the same age were compared in performance on an object sorting task (Mercado, Guerrero, and Gardner, 1963). The two groups differed somewhat in the types of categories formed with the objects, for example, the Mexican children made fewer categories than the U.S. children, but if single objects were not scored as categories, then the Mexican children made more categories with the objects. The general implications of these differences are not clear.

Gardner sees a close relation between the studies of cognitive control and Witkin's investigations of field dependence-independence and their development. In fact, one of Gardner's cognitive controls, "field articulation," seems to subsume the dimension of field dependence-independence, and two of its several measures are Witkin's rod-and-frame task and his embedded figures task.

Selective attention emerges as an important concept in Gardner's theoretical framework. This refers to a dimension of degree of attention to relevant though subtle aspects of stimulation rather than to irrelevant though compelling aspects in perceptual and cognitive tasks. Selective attention is viewed by Gardner as a crucial process in both Witkin's and his own studies.

A final note relevant to all of these investigations of individual differences concerns the problem of typologies. All three primary investigators—Kagan, Witkin, and especially Gardner—assert that the variables with which they are concerned are dimensions and not dichotomies. Nevertheless, in Kagan's and Witkin's work, and to a lesser extent in Gardner's, one finds these variables discussed at length as though they were categories of behavior. Kagan discusses reflective and impulsive types of individuals, and Witkin often discusses field-dependent and field-independent types of individuals. Furthermore, the nature of the studies conducted do not reveal whether the variables are dimensional or categorical. It would seem important to establish their nature early in the research programs. In short, it seems that studies of individual differences in perceptual development have not yet revealed any variables, either dimensional or categorical, which account for much of the subject variability in perceptual performance. It seems important to avoid the suggestion of dichotomies in this area until their presence is clearly established.

V DEVELOPMENT OF PERCEPTION OF COMPLEX EVENTS

Processing of complex information undoubtedly involves at least perception, learning, and cognition. It would be fruitless to try to draw a sharp distinction between the end of one process and the beginning of another.

In this section only the perceptual aspects will be emphasized

A. Perception of Moving Stimuli

There has been very little study of children's perception of real movement. As pointed out in Section II on sensitivity, the optokinetic response to a moving series of stripes has been used to measure acuity. The fact that even neonates exhibit such a response and the fact that they will track in the direction of a moving stimulus indicates an early gross sensitivity to motion. However, in these studies measurement of degree of sensitivity was not undertaken. Carpenter and Carpenter (1958) showed that two older children, 81 and 108 months, could discriminate between a stationary and moving stimulus. In this case speed of movement was varied and thresholds for detection of motion were determined. Edgren (1953) investigated the perception of motion in Ss from 8 years to old age. In many respects he replicated the classic work on this topic by Brown (1931). Brown had demonstrated that the phenomenal velocity of a moving stimulus varied as a function of distance, size of stimulus, and direction of movement, among other factors. Edgren presented the moving stimuli by means of motion pictures. Although this is not real movement, his results replicated the effects obtained by Brown with real movement for the variables of distance, size, and direction. The direction variable was the only one for which an age trend was obtained. Vertical movement was seen as faster than horizontal movement and this difference decreased slightly though significantly with age. Edgren suggests that the overestimation of vertical speed may be related to the fact that vertical distances are overestimated relative to horizontal as in the horizontal-vertical illusion. It might be pointed out as further support for Edgren's explanation that the horizontal-vertical illusion decreases with age (see Wohlwill, 1960).

There has been more direct concern with responsivity to apparent movement. Rock, Tauber, and Heller (1965) presented evidence that naive guppies and praying mantises respond with an optokinetic response to a sequence of illuminated stripes which are seen as moving by human adults, and Tauber and Koffler (1966) showed the same result

for human neonates. Harth (1966) also found that neonates respond to a sequence of lights which adults perceive as moving. His response measure was inhibition of sucking, which did not occur to a stationary light. Of course studying the perception of motion in nonverbal Ss poses a problem similar to that in studying the perception of depth: deciding whether differential response implies perception of the stimulus as *movement*. The optokinetic response as an index has some face validity for inferring that movement is perceived since the slow tracking component of nystagmus probably cannot occur (in humans) to discrete stimuli in different positions.

Older children, of course, can report when they see movement. Brenner (1957) presented to Ss ranging from 2½ to 19 years a pair of stimuli designed to elicit apparent movement. Each stimulus was presented for 25 ms and the interstimulus interval was varied. The presentation of the stimuli was repeated continuously to give the Ss an opportunity to make a judgment. In such studies, as the interstimulus interval varies from short to long, Ss' reports vary from seeing two *simultaneous* stimuli to seeing one stimulus *moving* between two positions, to seeing two stimuli in *succession*. The data can be analyzed in terms of the range of interstimulus intervals in which Ss report movement. In Brenner's study the midpoint of this range was a shorter interval for the younger children than for the older. In addition, the range was less wide for the younger than for the older.

Pollack (1966) also studied apparent movement with children from 6 to 11 years of age. His stimuli were presented for 50 ms and again the interstimulus interval was varied. He found a curvilinear relation between the midpoint of the range of intervals eliciting reports of movement and age, the midpoints were longer for the youngest and oldest children, decreasing to a minimum for the 9-year-olds. This age trend was due almost entirely to variation in the transition from reporting movement to reporting succession. The transition occurred at longer intervals for the youngest and oldest children and at shorter intervals for the 9-year-olds. The transition from reporting simultaneity to reporting movement occurred at a constant interval at all ages. Pollack suggests that the difference between

his and Brenner's results might be due to the very different stimuli used. For example, Brenner's stimuli were much larger, subtending a visual angle of 35° while Pollack's subtended only 2°. Such a difference might be reasonable from Pollack's point of view. He attributed the early downward trend in range midpoint to physiological age changes. If the crucial changes are changes in neural interaction in the peripheral visual system, they might well be manifest only over short distances on the retina, and so not be reflected in the perception of larger stimuli such as Brenner used.

Schiff (1965) examined the responses of a large number of species to an expanding visual stimulus. Animals from fiddler crabs to humans responded to an expanding shadow as if it were an approaching object. One S, a 5-year-old girl, consistently reported movement (as did the other human Ss) and in fact blinked and withdrew her head on several presentations.

In summary, it would seem that even young children are sensitive to movement and to stimuli eliciting apparent movement. The change in sensitivity with age needs more study. There are many other questions about perception of motion that have not been systematically explored. For example, investigation of children's sensitivity to trajectory of movement, their ability to extrapolate and predict time and point of impact might lead to interesting qualitative age differences in perception. A good review of the existing literature on these and related topics can be found in Gibson and Olum (1960).

B. Development of Language Perception

Little direct evidence is available about the early development of phoneme discrimination. Most of the ideas are based on inferences from such sources as the biographical studies of speech production (e.g., Velton, 1943; Leopold, 1939). Ervin and Miller (1963, pp. 111-114) have summarized the data from many of these studies and suggest some generalizations about the order in which phonemes are produced, for example, a vowel-consonant distinction is acquired first. These regularities in the development of phoneme production lend support to Jakobson's (Jakobson and Halle, 1956) hypotheses about the relation between distinctive or contrasting fea-

tures of phonemes and the order in which phonemes are acquired. For example, vowels and consonants differ by many contrasting features, and this distinction appears early in language development.

One Soviet study of phoneme discrimination is summarized by Slobin (1966, pp. 381-382). Shvachkin trained Ss to associate words differing by one phoneme with different objects. The results, for Ss between 11 and 23 months of age, implied that vowels generally are discriminated before consonants. The trends are similar to those for speech production. The available stimulus information, as well as the number of distinctive features, may be relevant for the development of phoneme discrimination. In one study with adults (Woodward and Barber, 1960) it was found that phoneme differences were most discriminable when both auditory and visual information was available (a sound movie), next most discriminable when only auditory information was presented (sound without film), and very poorly discriminated when only visual information was presented (film without sound). Perhaps the number of phoneme contrasts and their redundancy in terms of the perceptual modalities are factors in determining the developmental order in which they are perceived.

There is evidence, from the Haskins Laboratory, that adult acuity for detection of some phoneme differences is a matter of improved discrimination at phoneme boundaries rather than degradation of acuity within phoneme categories (Liberman, 1957). Considerable evidence has been amassed by this research group to the effect that phoneme identification is more closely related to units of speech production than to simple units of acoustical analysis. For a thorough review of this research program and a discussion of the theory of speech perception which underlies it, see Liberman, Cooper, Shankweiler, and Studdert-Kennedy (1967).

Finally, it is not surprising to find a relation between children's ability to discriminate speech sounds and their early reading achievement. Deutsch (1964) found that discrimination of speech sounds was better for good readers than for poor readers in the early grades. Since reading involves decoding written language into the spoken language, it is to be expected that individuals poor at dis-

criminating some of the speech sounds might also have difficulty learning to read

At the syntactic and semantic level of language development the evidence, again, is primarily from studies of language production and hence is, by necessity, inferential with respect to language perception. Yet one of the important questions to be investigated is just that relationship between perception and production of language. Another question concerns the units in which spoken language is processed and stored.

Spoken language appears to be salient auditory stimulation fairly early in development. Slobin (1966, p. 367) summarized a Soviet study of Fradkina which found that in infants of 10 to 11 months of age it was very much easier to condition a response to a word than to other auditory stimuli. Information about the auditory units in which spoken language is processed comes from several types of studies. Conditioning experiments show fairly consistent developmental changes in the type of word to which a conditioned response will generalize. Riess (1946) found maximum generalization to homonyms of stimulus words in 8-year-old Ss, to antonyms in somewhat older children, and to synonyms in children 14 years and older. Razran (1961) described some Soviet experiments providing more evidence that with increasing development, generalization of a conditioned response occurs more on a semantic and less on a phonetic basis. In one of these experiments Luria observed generalization in normal and mentally retarded children of the same age. Extremely retarded Ss generalized a CR only on a phonetic basis, normal Ss generalized only on a semantic basis, and moderately retarded Ss generalized to words both phonetically and semantically related to the conditioned stimulus word.

Slobin (1966, pp. 365-366) summarized an experiment by El'kin in which the conditioned stimulus was an entire sentence. He then observed the strength of generalization to parts of the sentence in children of different ages. For his youngest Ss, 10 to 12 years, generalization was greater to words at the beginning or end of the sentence, for Ss 12 to 14 years, generalization was greatest to the subject and predicate, and in the oldest Ss, 14 to 16 years, semantically important parts

of the sentences elicited maximum generalization.

The basis for the developmental changes found in these studies is not clear and one variable that might be involved is reading skill. Brown and Beiko (1960a), in an experiment that involved free associations and use of new words, found that words were increasingly associated with each other on the basis of a syntactic relationship as children became older. From first to third grade there was a marked increase in associations that were the same part of speech as the stimulus word as compared with associations that were a different part of speech.

These developmental changes in generalization of conditioned responses and in free word associations may reflect changes in the aspect of the stimulus complex on which attention is focused. With increasing development, it may be semantic and syntactic variables rather than phonetic variables which are attended to and are perhaps the units in which speech is processed and stored.

Other information about the units of auditory perception of speech comes from experiments using tasks which require Ss to attempt some type of analysis of words or groups of words. Zhurova, as summarized by Slobin (1966, pp. 385-386), required children to isolate and pronounce only the first or last sounds of individual words. In general, it was more difficult to isolate the final sound than the first sound. Three- to five-year-old children first had to pronounce the entire word before they could pronounce only the requested sound. Six- to seven-year-old children could produce the requested sound alone. Thus the older children could better analyze the sounds of the word, or at least focus attention on one sound segment of the word.

A task which, in some sense, is the converse of Zhurova's was used by Bruce (1964). He asked 5- and 9-year-old children to respond with the word remaining after a particular sound was deleted from a larger word. As in the previous task, performance was best when the sound was removed from the beginning of the word and next best when it was removed from the end of the word. The 5-year-old Ss apparently could not perform this task at all, but the 9-year-olds could. Al-

though it is difficult to compare age groups directly in these two studies, one might cautiously suggest that the task of producing the word remaining after a deletion is more difficult than producing the sound to be deleted from a particular location in the word. Perhaps the second task requires the capacity to analyze and focus attention on the sounds of the word separately, the first task requires, in addition, the capacity subsequently to change the focus of attention from the isolated sound to the remaining sounds.

Huttenlocher (1964) asked children to perform an analysis of word sequences rather than single words. Children of 4 and 5 years were asked to reverse two-word utterances, of various types. Pairs of words which comprised a common grammatical sequence were difficult for the children to reverse, whereas pairs of letters or numbers, words of the same part of speech, and words forming an anomalous grammatical sequence were relatively easier. It seemed that the ability to separate the members of a pair was a significant factor in determining whether the sequence could be reversed. Thus the capacity to focus attention on the separate elements was a necessary condition for performing another operation, reversal, on the sequences.

These three studies provide us with some information about the units of speech which can be attended to by children of different ages since the different tasks may require that attention be focused on part of the speech stimulus in order to successfully perform the task. The data considered thus far present a paradox: on the one hand, older children seem to process speech in more complex units than younger, on the other hand, older children are also better able than younger children to analyze speech into smaller units and separate sounds. It may be that this paradox is related to the development of attention (see Section VI). Perhaps older children are simply better able to focus attention on whatever aspect of the speech stimulus is relevant. Normally, this will be a larger rather than a smaller unit, but if the task requires, this will be as small a unit as a single speech sound. The importance of the task requirements is illustrated in a study by Anisfeld (1966) in which he examined children's knowledge of pluralization using three slightly different pro-

duction tasks and three different recognition tasks. The production tasks required Ss to produce various plural forms, whereas the recognition tasks required Ss to recognize the pictures to which various plural forms were appropriate. There were differences in difficulty among the two types of task, generally the recognition tasks were easier than the production tasks, but one of the recognition tasks was as difficult as two of the production tasks.

Two techniques used with adults might be adapted for use with children in order to tap more directly the perceptual processing of speech. Ladefoged and Broadbent (1960) and Fodor and Bever (1965) had Ss listen to spoken sentences and report the place in the sentences where an extraneous sound occurred. Sounds were frequently displaced to a syntactic boundary. In addition, if sounds were, in fact, located at a boundary, they were more often correctly perceived than when their actual location was in the middle of a linguistic segment. Mehler and Carey (1967) presented sentences against a background of white noise and asked Ss to write what they heard. Sentences differing in surface structure from those previously presented were inaccurately perceived. These studies demonstrated the effect on perception of linguistically defined units of speech. Whether the linguistic rules that affect perception will be the same for developing speakers and accomplished speakers should be investigated.

The precise nature of the relation between perception and production in language development is difficult to assess. Developmentally, there may be a lag between speech perception and production since the presence of such a delay between comprehension and production is quite well documented (e.g., Fraser, Bellugi, and Brown, 1963). The reasons for such a delay, such as S's interpretation of a task presented, are beginning to be investigated (Kaplan and Yonas, 1967).

The descriptive records of individual children's language development contain information about correlated changes in speech perception and production (Brown and Bellugi, 1964, Ervin, 1964, Brown and Fraser, 1964, Miller and Ervin, 1964). All such studies seem to agree that children's imitations of adult speech are shorter than the original, and that

the reductions are systematic. The parts retained in imitations seem to be the most informative parts. Whether the reduction is based on analysis of information, or whether the more informative parts are in certain locations in sentences and the locations are perceived, or whether the more informative parts are more discriminable because of a factor such as greater stress is not clear at present.

There has been a great increase recently in investigations focusing on reading and learning to read. This may reflect the increased national interest in remedial reading programs. Psychologically, it reflects the recognition of reading as a complex activity suitable for analysis in terms of basic perceptual and perceptual learning processes. Kolars, for example, described three levels of activity of a reader as including letter recognition, response to grammatical context, and perception of word meanings (Kolars, in press). His experiments with adult Ss have included studies of item recognition and of readability of text under a variety of geometric transformations (Kolars, 1968). He finds similarity for reading Hebrew and English in the order of difficulty of different transformations. He concludes that the transformation and not the orientation of single letters is related to the difficulty of reading transformed text.

Eleanor Gibson has conducted extensive theoretical and experimental analyses of the stages of reading and learning to read (Gibson, 1965, Gibson, 1969). In her view, the first phase of learning to read is acquiring the spoken language. Learning to read then involves learning to decode the written language to speech. This mastery of the written language proceeds through three generally sequential stages. The first is learning to discriminate among the written elements—the letters of the alphabet. Second, the child must learn to decode the letters to the sounds of speech. Finally, as he becomes a skilled reader he learns to use all the “rules” in the language such as spelling structure and grammatical structure. In short, he learns to process larger and more complicated units of the written language. Gibson and some other investigators have conducted experiments bearing on the perceptual learning processes of each of these levels and they will be discussed in that order.

The developmental course of letter discrim-

ination was investigated in the study by Gibson, Gibson, Pick, and Osser (1962) discussed previously. Improvement in such discriminations occurred between the ages of 4 and 8 years. The rates of improvement depended on the type of discrimination involved, that is, whether or not the difference was critical for distinguishing among real letters (see Section IB).

The question of whether this improvement in letter discrimination with age might reflect some type of learning was asked in a study by Pick (1965). She trained kindergarten children to make discriminations among standard letter-like forms and various transformations of the standard forms. Then, in a transfer task, the Ss made discriminations among forms which were either (1) the same standard forms as in the training stage, but new transformations (prototype group), or (2) different standard forms from those in the training stage but the same types of transformation (distinctive feature group), or (3) different standards and transformations from those in the training stage. The performance of the second group, whose members discriminated among forms they had never seen before but which varied among each other on the same dimensions as their training stage forms, was superior to that of the other two groups. Thus improvement in discrimination of forms like letters might primarily involve learning to attend to and respond on the basis of dimensional differences among the forms.

In another study Gibson (1965) found that for 4-year-olds, difficulty of matching real letters was highly related to the difficulty predicted on the basis of an analysis of the number of differences or distinctive features distinguishing one letter from another. Three studies investigated the utilization of such distinctive features in tasks of searching for a visual target letter (Gibson and Yonas, 1966a, 1966b, Yonas and Gibson, 1967). These are described in detail in Section VIC. These studies generally imply that distinctive features of letter forms rather than letter names or Gestalt shape variables are the basis for improved discrimination of the forms as a function of age and experience.

Once the letter forms are perceptually distinguished, the beginning reader is faced with the problem of decoding the graphemes into speech sounds. Bishop (1964), in an experi-

ment with adults, compared the effect of letter-sound training with word training on performance in learning a new list of nonsense words. In a paired associate task, Ss either learned to associate single sounds such as *fa* with Arabic graphemes (phonics method) or they learned to associate two-syllable nonsense words such as *faru* with written words composed of two Arabic graphemes (whole-word method). Following training to a criterion, Ss in both groups were presented with a second paired associate task in which the items were two-syllable words to be associated with two-grapheme written words. The two-syllable words, both in the whole-word training list and in the transfer list for both groups, were composed of the letters and sounds used in the single-letter training. Ss trained with the single letter-sounds learned the second word list faster than Ss trained with a list of words. Furthermore, the basis for transfer appeared to be the letter-sound relationships regardless of whether Ss had been trained with them or whether they had abstracted them from the list of words. Jeffrey and Samuels (1967) recently replicated this finding with kindergartners. They found a significant effect of letter training on correct responses on the first transfer trial as well as in number of trials to learn the new list. On this latter measure, Ss receiving word training were no faster at learning the second list than a control group of Ss who had received no training.

The units of processing at a more complex and skilled level of reading are surely not single letters. Adults find it extremely difficult to read material which is presented one letter at a time sequentially (Kohlers and Katzman, 1966, Newman, 1966). There is no particular reason to suppose that children who have attained some skill in reading find it any easier to process written text letter by letter.

The question of what the higher-order perceptual units of skilled reading are has been investigated in a number of experiments. Gibson, Pick, Osser, and Hammond (1962) found that for adults pseudo-words constructed according to the rules for English spelling were more easily perceived than pseudo-words which were not. The hypothesis entertained in this experiment was that the complex spelling-sound relationships define perceptual units in written material. The results of this experi-

ment have been replicated with children (Gibson, Osser, and Pick, 1963), with Braille readers (Pick, Thomas, and Pick, 1966), and with deaf readers (Gibson, Shurcliff, and Yonas, 1966). A variety of control procedures ruled out the possibility that some type of frequency of occurrence variable accounted for the ease with which the one group of words was perceived as compared with the other (see also Gibson, 1964). Since the deaf readers performed like the other Ss, and since they could not utilize the sound correspondence, it may not be the spelling-sound correspondences which operate as perceptual grouping principles but instead the spelling patterns themselves. Most of these Ss did not speak either though, and they may have learned to read in a manner quite different from normal readers. The question of the usual function of the sound relationship in forming larger perceptual units of written material is not settled by testing the deaf Ss. Bever and Bower (1966) are investigating the possibility that some readers may directly perceive written material ("visual readers"), whereas others perceive it in terms of the sound relationship.

The way in which the spelling patterns are learned is a problem only recently studied. Wallach (1963) found a significant positive relationship between fifth graders' spelling achievement scores and their accuracy in tachistoscopic recognition of letter sequences approaching real English words (e.g., *mossia*, *everal*) as compared to random sequences of letters. He interpreted this relationship as suggesting that spelling skill consists of learning the sequential probability arrangements of letters. Of course, the relationship could also be a function of learning spelling-sound regularities. Perhaps if Wallach had used nonsense letter sequences consisting solely of English spelling-sound regularities (instead of approximations) as compared with random letter sequences, the relationship between spelling skill and recognition accuracy would have been even greater.

Gibson, Farber, and Shepela (1967) studied directly the way in which spelling patterns might be learned. They used a learning set procedure and asked whether regularities in spelling patterns could provide a basis for improvement in performance across problems. The Ss were in kindergarten and first grade,

and each problem was a pair of four-letter words or pseudo-words. The correct members of the pairs contained a common two-letter pattern in a given location. The incorrect members of the pairs differed from the correct members by only one letter. The results from the kindergartners were difficult to interpret since they could not pay attention to the task, but the first graders did form learning sets with the material. That is, they showed the improvement over problems that one would expect if they were basing their responses directly on the structural regularities and looking for such regularities in new problems.

The function of grammatical structure in processing written material has been the subject of some recent investigations. Levin and Mearns (1964) proposed the hypothesis that attention tends to be focused on those parts of a word that are more important or informative. Specifically, they hypothesized that Italian readers would attend more to the ends of words than English readers because there are more inflectional suffixes in Italian than in English. They presented children who were either English or Italian readers with a sorting task consisting of a number of nonsense words in which the location of the critical attribute varied. The two groups performed equally well when the critical attribute occurred at the beginning of the words, but when it occurred at the end of the word the Italian children performed better than the American children. Here the grammatical structure of the language seems to function to direct attention to one or another part of a word.

The technique of measuring the eye-voice span (EVS) has been used by Levin to investigate the function of grammatical structure in perceptual processing of written text with children and adults. This technique measures the "distance" that the eye is ahead of the voice in oral reading. The distance is determined simply by removing the text from an S while he is reading aloud and then counting the number of words he is able to report correctly. With unstructured lists of words the number of words in the EVS remains quite constant for a given S, but with sentences the size of the EVS varies with structural characteristics of the sentences (Levin and Turner, 1966, Levin and Kaplan, 1966). For example, these studies found that the EVS

tends to reach to the end of a phrase rather than stopping before the phrase boundary. The EVS is shorter in active sentences than in comparable passive sentences, which are more constrained or predictable. Generally, the EVS increases with age and it is greater for fast readers than for slow ones.

The question can be raised as to whether these various grammatical constraints affect what the S can report by guessing on the basis of probabilities or whether they really affect what the S sees. That the effect is on the perceptual process and not just on facility of guessing is implied strongly by additional measures used in the Levin and Kaplan study. Ss were given a recognition test in which some of the words were from the experimental material and others had visual and semantic similarity to the experimental words. On this measure, the ratio of correct to incorrect recognitions was extraordinarily great. If the Ss are merely guessing when the EVS measures are taken, one might expect many of the guesses to be words visually and semantically similar to the correct words. On the other hand, it is possible that the correct words would have been highly probable guesses.

Sensitivity to grammatical context in oral reading was demonstrated in very young children by Weber (1967). She had first-grade children read aloud and she noted the errors they made. When an error was not compatible grammatically with the text, the children usually corrected it. On the other hand, if an error was not corrected, it usually proved to be grammatically compatible with the context. The better readers demonstrated these effects even more strongly than below-average readers.

The units of perceptual processing of written material again are obviously not single letters. Spelling structure (whether because of its relationship to speech patterns or independently of this relationship) and even more complex grammatical structure seem to operate in the formation of perceptual units in reading. Presumably, the skilled reader comes to be able to utilize more and more of these regularities of structure in the written language.

Just exactly how a reader progresses toward processing higher order and more complex units of material is not clear. Hochberg

(1966) has suggested that this perceptual learning involves changes in the way in which the material is coded and stored rather than changes in what is perceived. He had Ss make same-different judgments between pairs of written words presented either simultaneously or successively. In simultaneously presented words, if the shapes of the members of a pair differed (e.g., one in upper case, the other in lower case), response latency increased. When the words were presented successively, however, shape variables were irrelevant, but response latency increased if the words were unpronounceable or if they were presented in a geometric transformation. Presumably, shape differences affected the judgments in simultaneous presentation conditions by requiring S to read the words before making his judgment. Under successive presentations, when memory became involved and S had to read the words anyway it was not form variables but the variables affecting codability or readability which affected response times. Hochberg, in effect, suggests that changes in selection and attention and in coding are involved in the progression toward perceptual processing of increasingly complex structural regularities. Posner (1967) has utilized this type of technique in investigating the type of processing involved in perceptual matching, identification, and classification tasks in adults. This would also be a technique useful for such work with children.

Some studies have investigated the relationship between reading performance and other perceptual tasks. Buch and Belmont (1965) presented a task of auditory-visual matching of dot patterns to children from 5 to 12 years. Performance improved with age and most of the improvement occurred during the first couple of years. At these early age levels, but not later, task performance was also related to reading achievement. This result probably reflects the fact that the tasks required in reading change as the reader becomes more skilled. In a similar study, Muehl and Kremenak (1966) also found a high relationship between first graders' reading achievement and auditory-visual matching of dot patterns. To the extent that reading involves two modalities, it seems reasonable that other tasks involving the same two modalities show some relationship with reading. However, it might be observed that the pro-

cesses involved in recognition of dot patterns may not be similar enough to reading to elucidate the specific tasks involved in learning to read.

One final problem of perception and reading deserves some consideration. This is the relationship between tachistoscopic training and speed of reading. Most of the mechanical devices used in the "speed-reading" training programs—paceis, tachistoscopes, etc.—are assumed to be training eye movements and thereby increasing the speed of reading. Tinker (1958), in reviewing studies attempting to evaluate the effectiveness of these methods, concludes that systematic practice in reading results in as much improvement in reading speed as any programs involving mechanical devices. He also points out that changes in eye movements reflect but do not cause improvement in reading skill. Most of the relevant studies (e.g., Glock, 1949; Manolakes, 1952) used adult Ss and found no difference between the effect of specific training programs using tachistoscopic devices and systematic practice. One study (Manolakes, 1952) found a greater increase in words read per minute for Ss who practiced than for Ss who underwent the training program. It is doubtful whether the results of such studies would be different if children were used as Ss since Tinker's analysis of the eye movements as symptoms seems quite reasonable.

C Eidetic Imagery

An eidetic image has traditionally been defined as "a visual image of a figure, usually long in duration, localized in space in front of the S's eyes, positive in color, and usually in the plane where the original figure was shown" (Leask, Haber, and Haber, 1968, p. 1). The study of this phenomenon was once an extremely popular topic, but it received very little attention after 1932 (Kluever, 1932) until recently when Haber and Haber (1964) made the initial report of an extensive research program.

The Habers and their colleagues, in contrast to many of the early investigators, have done a very careful job of operationalizing criteria for the definition and identification of eidetic imagery. In the initial study (Haber and Haber, 1964) 12 of 155 school children reported a degree of imagery which was far superior on a number of measures than 72

others who had reported some imagery. For example, in these 12 children all images of the pictures displayed lasted longer than 40 seconds, their accuracy scores were higher, a much greater percentage of the images were positively colored, and all of them could be scanned with their eyes (as opposed to the image moving with the eyes). These results proved reliable on retesting after 8 months. A subsequent screening of 380 school children yielded 23 who seemed to have a reliable, qualitatively different kind of imagery (Leask, Haber, and Haber, 1968).

On the basis of subsequent work and overall examination of the data these investigators have suggested even more stringent criteria for identification of eidetic imagery. One possibility they have developed is to show an S a sequence of two meaningful pictures which can be superimposed to make a quite different picture. If an S has an eidetic image of the first picture and superimposes it on the second, he should be able to report the composite picture. When the 23 Ss who were thought to be eidetic were shown the sequence of two pictures, only 4 responded appropriately. In addition, 2 Ss with high eidetic imagery were matched with two control Ss in school grade and academic ability and were tested on their ability to report from the image or recall details of pictures that they were shown. The accuracy of all 4 Ss was approximately the same, suggesting that a criterion of exceptional memory may not turn out to be as important a distinguishing characteristic as was once thought. The investigators feel overall that there is a reliable phenomenon of eidetic imagery that occurs with a lower frequency than was thought on the basis of the early literature. This phenomenon deserves to be studied, especially in light of the current interest in various types of memory processes.

On the basis of the Habers' work there seems to be little evidence for a decrease in eidetic imagery with age, although this was a very common report in the early literature. It should be pointed out that the Habers have both cross-sectional and longitudinal data relevant to this question. Relevant to individual differences is a report by Sipola and Hayden (1965) of a very high incidence of eidetic imagery in a brain-damaged retarded sample of Ss. Doob (1966) has reviewed a

number of studies of eidetic imagery in different cultures. The incidence varied from 0 to 20% in the various cultures.

The study of imagery, eidetic or other, is complex. To conduct such research with retardates or cross-culturally must multiply the difficulties. Nevertheless, the careful methodology of the Haber group provides a model for how to proceed.

VI. DEVELOPMENT OF ATTENTION⁴

Attention concerns the motivation of perception, its selectivity and maintenance. The study of attention has had an erratic history in general psychology, assuming central importance in the days of the structuralists (see Boing, 1950) and being virtually ignored from the 1930s to the 1950s. The study of attention revived from the impetus given during the war to studies of vigilance of watchstanders. The study of the development of attention must be marked as part of the general interest in perceptual development.

A. Stimulus Determiners of Attention

Fantz (1958), in one of his early studies, observed infants' fixation preferences when they were shown a pair of figures, he noted that infants tended to show a preference for a more "complex" figure over a "simpler" figure. However, he also noted that the preference shown for a horizontally striped figure compared with a checkerboard figure showed a reversal at about 2 months of age. Fantz' definition of complexity was an intuitive one and a great deal of research with infants has been conducted using variations of his technique to ascertain the precise stimulus variables that are implied by this term. Complexity as measured by information content, novelty, amount of contour, and brightness has been investigated as a possible determinant of attention in infants. The reader is referred to Chapter 10 for details of many of these studies. One carefully controlled study (Bren-

⁴ A promising and exciting approach based on concepts of information processing related to this section and Section IVA on perception and intelligence is exemplified by Neisser's (1968) book, *Cognitive Psychology*. Unfortunately, to date little developmental work has been done relevant to Neisser's ideas.

nen, Ames, and Moore, 1966) indicated a curvilinear relationship between fixation preference and complexity. The maximum duration of fixation occurred for stimuli of medium complexity. Stimuli of greater and lesser complexity elicited fixations of shorter duration. The point of maximum duration moves toward more complexity as a function of age between birth and 6 months. In this case complexity was defined as number of squares in a checkerboard pattern. A similar shifting curvilinear relationship was found by Sackett (1966) with infant monkeys. In his case complexity was defined as amount of contour change per unit area. This definition of complexity is congruent with that of Biemmen et al (1966) applied to their stimuli.

There have been a number of developmental studies of older children which have varied such dimensions as stimulus complexity and have measured reported stimulus preference rather than fixation preference (Cantor, Cantor, and Dittrichs, 1963, Clapp and Eichorn, 1965). In one study (Munsinger, Kessen, and Kessen, 1964) a paired comparison design was used to evaluate the preference for pairs of random forms which varied in number of corners. The pairs of stimuli were presented to children in the first to eighth grades. In each case they were asked to indicate which of the two forms they preferred. The older children showed maximum preference for 10-cornered stimuli and decreasing preference for stimuli with more or fewer corners. This replicated a previous result with adults (Munsinger and Kessen, 1964). On the other hand, the younger children showed increasing preference with increasing number of corners. However, they did show a secondary preference peak for 10-cornered stimuli. These investigators hypothesized that stimulus preference is determined by an optimal complexity level which matches an information processing level of the organism. Since this would be expected to increase with age, the results of the younger children do not support the hypothesis. However, in the second part of the study the same procedure was used with letter sequences which varied from complete redundancy (repetition of the same letters) to maximally informative (random letters). Here maximum preference was shown by all ages for intermediate levels of redundancy with older Ss showing somewhat

higher preference for the less redundant material. These results support the initial hypothesis.

Thomas (1966) reported a similar study including two experiments that cover an age range from 6 to 19. His stimuli were generated by the same method used by Munsinger, Kessen, and Kessen. He measured preference for a stimulus initially by noting whether S fixated it longer than the stimulus with which it was paired, and 2 weeks later by a direct judgment of preference. These two measures were in very close agreement. The results indicated that, for younger children up to about 12, preference was an increasing function of complexity, defined as number of turns of the stimulus. Above this age the relationship between preference and complexity was curvilinear, with the maximum preference occurring at decreasing complexity values as age increased. Thus Thomas' results agree with those of Munsinger, Kessen, and Kessen with similar shapes, except for the particular age at which complexity values for maximum preference start to decrease. A completely satisfying explanation for these results is yet to be found. Thomas does make an interesting observation that older Ss show more inconsistency in their judgment, as indicated by lack of preference transitivity (Stimulus A being preferred to stimulus B, and B to C, does not necessarily imply that A is preferred to C). He suggests that different aspects of the stimuli may determine the preferences at different times. The results for complexity may not be generalizable to other kinds of stimuli. Clapp and Eichorn (1965) found no relationship between looking time of nursery school children and complexity (stimulus redundancy) when the stimuli were geometric forms varying in regularity. However, their study also differed from the ones just discussed in that stimuli were presented successively rather than in pairs. They did find that colored stimuli elicited longer viewing than black and white and that incongruous stimuli (e.g., a picture of a bird with two bodies and two heads but one pair of legs) elicited longer viewing time than normal stimuli.

Selectivity of perception can also be determined by other aspects of the situation than the stimulus itself. Reese, for example, presented a series of human or of animal pic-

tures prior to exposure of an ambiguous figure (which could be seen either as a man or a rat). He found a preponderance of responses consistent with the forms previously shown (Reese, 1963a, 1963b, Reese and Ford, 1962). The Ss ranged in age from preschool to second grade and the result was stronger in the older children. Reese attributed the results to a mediation process by which an expectancy for the class of stimuli previously exposed causes a bias in coding the incoming stimulus. However, the mediation process may be simpler than the one implied. Exposure to a class of stimuli may cause S to attend to different parts of the stimulus than he would with another class of stimuli. This would put the selectivity in the perceptual rather than the response aspect of the identification.

Reese's suggestion of a mediating process for perceptual responses is related to the acquired distinctiveness hypothesis formulated succinctly by Miller (1948). This hypothesis suggests that if different responses are associated with two stimuli, the stimuli will become perceptually more different. This occurs because there are different responses produced to stimuli accruing to the initial stimuli. Conversely, stimuli which have similar responses associated with them become perceptually more similar. This phenomenon is called acquired equivalence. One way of studying this hypothesis has been to have Ss learn distinctive or common verbal labels for two or more stimuli and to observe whether this affects their discriminability. There have been numerous studies with this general paradigm, but they have failed to be crucial for the hypothesis since they have (1) used as a measure of discriminability a learning task that involved association as well as discrimination, or (2) used stimuli that were initially very discriminable, or (3) not determined the discriminability of the initial stimuli. Recently, Katz (1963) reported a study not subject to these deficiencies, which provides positive evidence for the hypothesis. She taught 7- and 9-year-old Ss verbal labels for a set of four nonsense forms and then tested their discriminability using same-different judgments. One group of Ss learned a common label for each pair of forms. One group learned different labels for all four forms. A third group simply observed the forms and

did not learn labels. The discriminability of the forms was then tested by showing Ss pairs of forms tachistoscopically and asking them to make same-different judgments. The *common label* group made more errors in identifying two shapes as the same when they were really different, the *different label* group made fewer such errors, and the *nonlabel* group gave intermediate results. These results are the best evidence obtained to date for a change in perception as a function of such association. As Katz points out, the results do not agree with other studies which have properly measured changes in perception, but these were done with adults. Perhaps the design with children is a more sensitive test of the hypothesis.

B Maintenance of Perception

One of the traditional questions of attention is the extent to which a person is able to perform one task in the face of irrelevant stimulation, that is, distraction. The study of vigilance represents one extreme of this question. How well is a person able to perform one task over a long period of time in the absence of any extraneous stimulation?

There is a common hypothesis that mental retardates are more distractible than normal children. In this context Ellis, Hawkins, Preyer, and Jones (1963) investigated the effect of distraction on oddity problem learning (learning to pick the one of three objects which is different from the other two) in normal and retarded children between 6 and 8 years. The distracting condition was a mirror mounted on the apparatus and facing S. This distraction facilitated performance for the normals and had no effect for the retardates. On the other hand, Turnure and Zigler (1964) found that under certain conditions performance of retardates is facilitated by distraction. They used an object assembly task with 6-year-old retardates and found that a distraction was beneficial if it provided information which was subsequently useful, for example, when the distraction consisted of E working on a problem that was subsequently given to the child. Turnure (1966) used an oddity problem task and found that normal children 5½ years old were adversely affected by a mirror distraction, whereas the performance of older children was facilitated. He suggested that the distraction serves to

mobilize the energy of the older children toward the task. The mirror mounted on the apparatus would also serve to keep the child oriented to the task, but this should be true for younger children as well as older children. In the same study a distracting noise was also introduced for some Ss, but this had no effect on the performance.

The second type of distraction problem of current interest in general perception is the study of perception under simultaneous input of information from two sources. Such experiments most often have taken the form of simultaneous input of two auditory messages and are referred to as selective listening experiments. They derive most directly from Broadbent (1958), who suggests that when the information load becomes too great for immediate transmission through man's perceptual channels he has a short-term storage available to hold the excess momentarily. If the delay in transmission exceeds a rather short time, the information in this short-term storage is lost. He conceives of a filterlike model which permits a person to transmit some of the information directly through the perceptual channels and to shunt some of it into storage. One implication of this is that if two messages are given to a person at the same time, he could choose to listen to one and ignore the other. Many interesting experiments have been done to try to ascertain on what stimulus characteristics the filter would work. It has been found that adults can selectively listen with ease to one of two messages which differ in spatial location or in voice quality but not when they differ in semantic content (Triesman, 1964a, 1964b).

Maccoby and Konrad (1966, 1967) have conducted a series of selective listening experiments with children. In these studies children, ranging in age from kindergarten through sixth grade, were asked to repeat one of two simultaneously presented messages. The messages, one in a man's voice, the other in a woman's voice, consisted of one or two words. In the first study (Maccoby and Konrad, 1966) the messages were presented through earphones, and the effects of age, practice, type of presentation, and number of syllables in the stimuli were investigated. The children were told before each pair of messages to report either the man or the woman's voice. The results showed significant improve-

ment with age and significant practice effects through two series of trials. The type of presentation was varied by presenting the messages both through the two earphones and one through each earphone. In the second procedure, the messages differed in spatial location as well as voice quality, and it is this condition that produces better selectivity. The performance with messages differing in spatial location alone was not determined. Multisyllable words were recognized better at all ages, but had relatively more advantage for the older children. The authors suggest older children may be better able to use the redundancy in language.

In a second study (Maccoby and Konrad, 1967) a condition of preknowledge about the voice to be selected was compared with a condition in which the voice to be reported was indicated after the messages were transmitted. It was hoped that this comparison would reveal whether the selectivity mechanism functioned before or after the stimulus. In this study, the messages were presented over two loud speakers rather than through earphones. Again performance improved with age. Preknowledge appeared to aid performance for the younger children and not for the older. However, only a main effect of preknowledge was statistically significant. In various conditions the effect of the familiarity of target words and sequential probabilities of pairs of words in the target messages were also studied. Both of these factors influenced the accuracy of performance, and sequential probability interacted with age. The high sequential probability phrases were more effective for the older Ss than the younger Ss. The authors interpret this result to mean that the older Ss are better able to fill in poorly heard phrases. The two studies together yielded overall age differences in performance but, for the most part, not the interaction that would have indicated qualitative developmental changes in the selective process itself.

In another study using the selective listening technique Neufeldt (1966) presented two digits simultaneously, one to each ear. The S's task was to report all he heard on each presentation. A group of 13-year-olds reported significantly more digits correctly than a group of 9-year-olds. This was true for both the first half of their report and the sec-

ond, thus suggesting better perception and short-term memory for the older children. This interpretation is based on an assumption that if S is required to report all he has heard, performance on the initial half of the report (the first digit reported) reflects perception, whereas that on the last half (the second digit reported) reflects short-term memory. A group of organically brain damaged and a group of cultural-familial retardates, matched in MA to the 9-year-olds and in CA to the 13-year-olds, performed at approximately the same level as the 9-year-olds, suggesting that the differences found between the 9- and 13-year-olds is an MA difference rather than a CA difference. The 9-year-olds did significantly better than the organic retardates in the second half of their report, but not as well as the 13-year-olds. To the extent that the second half of the report does represent short-term memory, it suggests an IQ or developmental rate deficit.

In another experiment in this study, four stimuli were presented, one to each ear simultaneously, followed by a second to each ear. The Ss were directed to report the message either ear by ear, pair by pair (i.e., in temporal order), or by type (e.g., digit or letter, since in this case the messages were mixed digits and letters). In general, the 13-year-olds did better than the 9-year-olds. All Ss did relatively poorly reporting by pair. The normal 9- and 13-year-olds did equally well reporting by type or by ear, but both groups of retardates did better reporting by type than by ear. The author interprets this difference in performance as reflecting recall strategies. The normal Ss are relatively better able to shift recall strategies than the retarded Ss.

The possibilities of using the selective listening technique to explore developmental changes in perception and short-term memory have just begun to be exploited (see also Inglis and Caird, 1963, Broadbent and Gregory, 1965). However, developmental differences in selective listening may not be unequivocally interpretable since the process of selective listening is not completely understood for adults. Developmental studies will contribute to an understanding of the general process and vice versa.

The phenomenon of retinal rivalry has been thought to be a useful measure of attention in the sense of maintenance of perception.

This is the alternation between seeing one and another of two stimuli, presented simultaneously one to each eye (see Woodworth and Schlosberg, 1954). One developmental study of this phenomenon with Ss from kindergarten to college age has been reported. Goldstein and Cofoid (1965) presented a vertical line to one eye and a horizontal line to the other eye, and Ss were asked to report what they saw. They noted how many times during a 3-minute observation period the S's report changed. There was a significant increase in alternation or change as a function of age and a somewhat greater frequency of alternation for girls than for boys. Control experiments and careful instruction of the younger Ss ruled out the possibility that the differences were due to experimental artifacts. It seems surprising that a measure of attention would show a decrement with age. However, the task in this experiment did not ask Ss to maintain attention. Thus results obtained with this method, in fact, may not be relevant to that aspect of attention.

C Visual Search in Children

Woodworth and Schlosberg (1954) have reviewed the early literature on attention as measured by the number of objects that could be apprehended at a single glance (span of attention) and on changes of attention as indicated by number and loci of eye fixation. The final aspect of attention which will be considered here is visual search. There has been relatively little work investigating how children approach a perceptual search task. As in the case of investigation of shape perception (see Section IB), there are at least two possible strategies for studying search behavior in children. The exploratory behavior itself can be observed, for example, by recording and analysis of eye movements, or features of the search process can be inferred from measures of the results of search. Both methods have been used with children.

White and Plum (1964) photographed preschool children's eye movements while they performed a series of discrimination learning problems in a learning set design. The photographic records only permitted reliable judgments as to whether an S was looking right or left. Frequency of movements, defined as a change from looking right to looking left, was correlated with performance.

in the learning task. The total number of eye movements in a relatively easy, interesting problem series was greater than in more difficult series. There was some suggestion of an increase in number of eye movements until S reached a successful solution and a decrease thereafter. This seemed to be true for both intraproblem and interproblem performance.

Mackworth and Thomas (1962) devised an apparatus to photograph and measure eye fixation position to within 1° of visual angle ($\pm \frac{1}{2}$ inch at a distance of 28 inches). Such precision permits detailed analysis of where Ss look in a visual display. Mackworth and Bruner (1966) used this device for an intensive study of the eye movements of 6-year-old children and adults. The Ss viewed a series of photographs of a picture which was either progressively blurred or was initially blurred and progressively brought into focus. Each successive exposure of a picture in the progression lasted 10 seconds, during which time eye position was recorded. The Ss commented on the picture after each exposure. Overall results showed that average fixation duration is slightly longer for children than for adults (373 versus 360 ms).

The authors point out that these durations are longer than those typically found for reading and they do not decrease so markedly with age. They suggest that pictorial viewing is not so developed a skill as reading. All the Ss tended to focus their fixations on fewer points as the stimulus became more blurred. Intersubject variability was extremely high so that there was no group trend toward concentration on particular points of the target. Children also scanned less effectively by failing to attend to the most informative aspects of the picture. Furthermore, they were more variable in exploration of repeated presentations of the same picture. Finally, children made many more very short eye movements, relative to the number of larger saccades. This last fact is interpreted to mean that they restrict their intake of information when faced with tasks that put a burden on their capacity for information processing—in other words, children develop a kind of tunnel vision. These results are admittedly preliminary since they are based on a restricted collection of stimulus materials and a narrowly prescribed task. However, the feasibility of the tech-

nique has been demonstrated and the type of analysis is both precise and imaginative.

Vurpillot (1966) used Mackworth's recording technique to observe the eye movements of children from 5 to 9 years old as they made same-different judgments about pairs of stimuli. The stimuli were outline drawings of houses, each with six windows. Corresponding windows in the pair of stimuli could contain the same or different designs and the children's task was to decide whether the two houses were exactly the same. The eye movement recording was precise enough to be able to follow Ss' scanning as they looked from window to window. Vurpillot was able to infer the strategies that the children of different ages were using. She found that the younger children spend less time scanning than the older children before making their judgment. This is apparently due to reaching a decision upon incomplete sampling of the stimulus. The children of intermediate age scan for as long or longer than the older children. They are not as sensitive to the demands of the task, and even after they find a difference they will go on to scan the whole array before making a judgment. Some of the different behaviors of children apparently reflect differences in short-term memory capacity. For example, more older children will scan several windows in one house before scanning the corresponding windows in another house.

There has been some work on search patterns in tactual exploratory behavior and this has been described previously (Section IB) in connection with shape discrimination. In addition, Glaser (1965) has shown that it is possible to reinforce the exploratory movement of the hands in tactual exploration so that children will explore texture cues or shape cues. As might be expected, such training can have a facilitating or inhibitory effect on discrimination learning, depending on relevance of the trained cues for the learning task.

Gibson and Yonas (1966a, 1966b) have conducted studies which are good examples of the way in which aspects of the search process can be inferred from the results. These investigators used a task originally devised by Neisser (1964) to study differences in search between children and adults. The task is to search through a list of rows of

letters for a target letter. The farther through the list an S has to search, the longer is his search time. It is possible to calculate the average time for processing each letter and to study the effect on this time of such parameters as age, number of targets, confusability of the contextual letters.

In the first study (Gibson and Yonas, 1966a) Ss searched for one or two targets against a low confusion background, that is, a background of letters that are rarely confused with the target letter. In another condition the Ss searched for one target, which was embedded in a highly confusable background. Children from the second, fourth, and sixth grades and college sophomores served as Ss. Response time decreased significantly with age, and the low-confusion background produced shorter response times than the high-confusion background. However, there was no effect of number of targets nor was there an interaction of age with confusability or number of targets.

In a second study (Gibson and Yonas, 1966b) third-grade and college students searched for targets, again in the context of high- and low-confusion visual backgrounds. In addition, however, high- and low-confusion auditory backgrounds were introduced by presentation of spoken letters through earphones. In this experiment only the visual backgrounds affected search time, as in the first study, the high-confusion background resulted in longer response times. Interestingly, in the second study there was an interaction between the age and confusability of visual background. The children's response time was more severely affected by the high-confusion background than was the adults'. As the authors point out, this result may not have been found in the first study because of uncontrolled order effects. The investigators suggest application of this technique to a microanalysis of the strategies involved in the search process. By varying the number of distinctive features shared by the target and background letters, they hope to be able to infer the strategies utilized by children and adults in such tasks. Preliminary results by the same authors (Yonas and Gibson, 1967) from disjunctive reaction time procedures support the hypothesis that number of shared features between target and nontarget stimuli

is an important determinant of information processing time.

D. Perceptual Learning and Attention

Many different problems have been discussed in this section on attention. There is no general theory that attempts to encompass all of them. Indeed it is quite likely that at least the *maintenance* aspects of perception involve quite different processes than the *selective* aspects. The theoretical position of Eleanor Gibson, however, is one that focuses on the selective aspects of perceptual learning and development. One basic tenet of this position is that perceptual development consists of a progressive increase in sensitivity. This increase in sensitivity refers to both an increase of resolving power with respect to single stimulus dimensions and an increase in the number of stimulus dimension to which a person is sensitive. An example of the type of improvement predicted from this point of view is the results of the normative study by Gibson et al. (1962) of shape perception previously described (see Section IB). In that study, it will be recalled, children were asked to discriminate between standard forms and various transformations of them. Improvement with age occurred for discrimination of all the transformations reflecting an increasing sensitivity within specific stimulus dimensions. The different levels and rates of improvement for the different types of transformation were attributed to differential sensitivity to the various stimulus dimensions. For example, topological differences between stimuli ordinarily specify different objects in the world, and children early exhibit sensitivity to this type of difference since it is necessary for their real-life perception. On the other hand, perspective differences are typically found in the real world when the same object is seen from different viewpoints. Thus there is little reason for children to have an early sensitivity to this type of difference. The crux of this interpretation is that children are and become sensitive to specific stimulus dimensions and this sensitivity generalizes under appropriate conditions.

This interpretation was investigated in the previously cited study (see Section VB) by Pick (1965). It will be recalled that when kindergartenners were trained to discriminate

visually between standard forms and transformations of them, then learning appeared to be based on detection of distinctive features to a greater degree than on construction of prototypes or templates. The generality of these results to tactual perception was explored in the same study. Pick used essentially the same design in replicating the experiment under conditions of simultaneous as well as successive tactual comparison of the forms. When the comparison was simultaneous only distinctive feature learning occurred, when the comparison was successive both distinctive feature and prototype learning occurred. The author suggested that distinctive feature learning, which always occurred, was basic to such improvement in sensitivity. Prototype learning occurred only to the extent that memory was involved in order to compare one form with another. The importance of distinctive feature learning was also demonstrated in cross-modal replications of these experiments (Pick, Pick, and Thomas, 1966). The learning and generalization of distinctive features may be a very important way in which improvement in sensitivity occurs.

From Gibson's point of view sensitivity or changes of sensitivity could be built into the organism or could develop as a function of experience. It is essentially neutral with respect to the nativism-empiricism controversy. However, to the degree that experience is necessary for improvement in sensitivity, it does not function by association. That is, we do not perceive better or differently because we add meaning or implicit responses to the stimulus input. We perceive better because we have become sensitive to more or different properties of the stimulus. The kind of experience that will lead to improvement in perception is any experience that provides the opportunity for detection of more of the stimulus properties. This may, but does not have to be an identification learning task such as is used in traditional discrimination learning studies. Scanning the stimulus, for example, is at least as conducive to an improvement in perception. An experiment illustrating the expected results is one reported by Robinson (1955). He presented adult Ss with 10 fingerprints as stimuli in a study of the transfer of different kinds of training to a subsequent discrimination task. One group learned a different gang-

ster name for each print, another group learned to respond with "cops" to five of the prints and with "robbers" to the other five. A third group made same-different judgments among the fingerprints. In a transfer task requiring same-different judgments between fingerprints, all three of these groups made significantly fewer errors in a transfer task than a control group, which had received no training. The differences between the training groups were not significant. These results suggest that same-different training is as effective for improvement in discrimination as is training to associate distinctive labels. They are not congruent with the previously described results of Katz (1963), who, it will be recalled (see Section VIA), found that association training resulted in differential effects as compared with nonassociation training. The reasons for this incongruity are not known. Gibson would interpret the improvement in discrimination such as found by Katz also to be a function of learning to attend to the relevant properties of the stimuli rather than a direct function of association training.

Description of the mechanism for the detection of stimulus properties has been a problem in the theoretical position proposed by Gibson. However, recently (Gibson, 1969) she has attempted to specify the form of such a mechanism in more detail. She suggests that, peripherally, overt orienting or exploratory movements may mediate attention to the various features of the stimulus. (It cannot be emphasized too strongly that in Gibson's point of view these overt responses do not operate by changing the stimulus input after it comes in, but by causing a different stimulus to come in.) At the level of the central nervous system, Gibson suggests the existence of an abstracting process and of a filtering process similar to that suggested by Broadbent (1958). The nature of the abstracting process still lacks satisfying specificity. However, the filter model, by virtue of the work of such investigators as Broadbent (1958) and Triesman (1964a, 1964b), is quite meaningful. That is, the properties of one kind of filter model have been well investigated, but there is no equally well formulated model for the abstraction process. In referring to such processes Gibson points out that although the direct evidence for them is scant, there are many converging lines of

evidence, which make their existence extremely likely. The reader is referred to Gibson's (1969) book for a development of this theoretical orientation including a careful review of the evidence and a consideration of the implications for a variety of interesting problems.

VII THEORIES OF PERCEPTUAL DEVELOPMENT

Several theoretical points of view have been described in discussing specific topics in perceptual development: those of Brunswick, Gibson, and Pollack, the sensory tonic concepts of Werner and Wapner, Gestalt theory, the Soviet motor-copy view, and the individual difference approaches of Gardner, Kagan, and Witkin. It was thought that the research problems might be better integrated in the context of a theoretical perspective. However, it is apparent that the theories are not formal hypothetic-deductive systems but are more or less specific frames of reference for examining problems of perceptual development. This generalization is also true of a few additional points of view to be described.

All these theories may be compared on a number of dimensions. Several positions have already been characterized as being nativist or empiricist, or as involving mechanisms of enrichment or differentiation. They may also be characterized along an active-passive dimension. That is, many theories consider S's gross activity to be involved in perception, whereas others would consider S's to be relatively passive receivers of sensory information. Finally, and in many ways most importantly, the various theories differ greatly in the problems toward which they have been directed and the research which they have stimulated. The ideas of Piaget, Hebb, and a neurophysiological approach to perceptual development will be examined with these distinctions in mind.

A. Piaget

Flavell (1963) quotes the following definition of perception by Piaget. "We will call perception the most direct or immediate possible knowledge of a present object in the sensorial field (without affirming, however, that there exists a knowledge which is completely direct or immediate)" (p. 232). This

definition has two important implications for the present purpose. First, it focuses attention on knowledge by perception and on knowledge by means other than perception. Illusions lend themselves very nicely to such a distinction. Illusory perception can be corrected by cognitive operations. Second, the implication in the definition that perception is not an immediate process raises the question of the perceptual process as it develops over time. It is with respect to this question that Piaget's mechanism of perception becomes apparent. The longer the duration of fixation of a stimulus, the larger it will appear. Such a relationship obtains because subjective size is conceived to depend on the number of interactions or encounters between elements of the stimulus and S's receptors, and the number of such encounters presumably increases with fixation time. When two stimuli are presented, the degree to which one is overestimated relative to the other depends on how the encounters of each stimulus are combined or coupled. The more such coupling is complete and balanced, the more veridical will be perception of relative size. Thus the effect of coupling is opposite to that of fixation. Errors involving the original encountering due to fixation are called Type I and, as indicated, often are in the direction of overestimation. These errors decrease with age. However, S's perceptual activity such as eye movements and scanning strategies control the completeness and balance of coupling.

The perceptual activity can also lead in some cases to nonveridical perception. Piaget speaks of such cases as Type II errors. These often increase as a function of age with an increase in S's perceptual activity. Examples of such errors include size constancy studies, which often produce results in the direction of overconstancy with increasing age, and figural aftereffects, the magnitude of which also appears to increase with age. Piaget's model, which he has developed in mathematical form (described in detail by Vurpillot, 1959), has been mostly applied to illusions. However, he has also applied it to psychophysical thresholds and it is possible to derive the Weber-Fechner law from it.

A study of an illusion which illustrates Piaget's interest in comparing perceptual and cognitive modes of knowing was reported by Piaget and Taponier (1956). If two equal

parallel horizontal lines are presented so that they are laterally offset, the upper line is overestimated relative to the lower. Piaget and Taponier found that the degree of this overestimation increases as a function of age. However, when the lines are presented initially directly under each other so that no illusory effect occurs and are then displaced while *S* is watching, the task becomes one of conservation of length. In this case with increasing age, decreasing number of *Ss* make illusion-type judgments, which would be expected since there is increasing length conservation as a function of age. The procedure of comparing increasing *magnitude* of illusion with decreasing *numbers* of *Ss* exhibiting the illusion may be questionable. Nevertheless, it is an interesting demonstration of perceptual and cognitive development showing opposite age trends.

Piaget's interest in perceptual activity is illustrated by one of the most methodologically precise studies coming from his laboratory (Piaget and Vinh-Bang, 1961). This study was an investigation of temporal parameters of eye movements and fixations during a number of perceptual tasks. Such information presumably could provide precise empirical support for the effects of fixation and coupling. For example, when the perceptual task was to compare the lengths of two vertical line segments, one above the other, there was a tendency to overestimate the upper segment. Eye movement analysis indicated the upper segment was fixated more often. However, in general the lack of details about reliability of the measures makes interpretation of this study difficult.

Piaget's explanation of perception then is based on perceptual activity in the sense that Type I errors occur because of fixation duration and Type II errors because of changes of fixation or scanning. Pollack, as will be recalled, has also focused on developmental changes in illusions and, like Piaget, distinguishes between those that decrease and those that increase with age. However, in Pollack's view the mechanisms are quite different, being basic physiological aging factors for the second type.

B Hebb

Hebb (1949, 1958), like Piaget, tends to emphasize activity in his analysis of percep-

tual development, although, like the Gestalt theorists, he considers the discrimination of figure and ground as a primitive basis for perception. He conceives of perception as a mediating process between sensation and response and his views of perceptual development concern the role of early experience in producing this mediating process. Perceptual activity is brought into the theory by invoking the hypothetical physiological entities of cell assembly and phase sequence. These concepts refer to integrated neural networks formed by the close association in time between stimulus configurations and receptor organ (e.g., eye) movement. In Hebb's view the formation of such neural networks is a prerequisite for any pattern perception. Thus even very primitive aspects of perception depend on prior experience and movements or scanning. It is not surprising then to find that much research conducted or stimulated by Hebb has investigated the effects of early perceptual experience. In the absence of prior visual experience, pattern perception should be very difficult. Hebb discusses studies of dark-reared animals and congenitally blind humans who have had their sight restored (Senden, 1960) and adduces evidence that under these conditions pattern perception is indeed defective (see Section IC). However, the human evidence is often very ambiguous (Wertheimer, 1951) and Gregory and Wallace (1963) have recently described a relatively clear counterexample—a case of a patient with restored sight who was able to make good shape identifications very soon after recovery of sight.

Another direction of work stimulated by Hebb has been examination of the perceptual effects of scanning tendencies. Highly practiced scanning movements in one direction may facilitate information reception in the direction of scan. Thus when single letters are flashed tachistoscopically to the left or right of a fixation point they are detected more accurately on the right. Furthermore, this selectivity increases with age (Forgays, 1953). It is as if the left-to-right scanning of reading habits makes one more sensitive to stimulus input from the side toward which the eyes are moving. It will be recalled that in her studies of perception of orientation, Ghent similarly suggested that *Ss* tried to scan from top to bottom of stimuli. When this scanning tendency is not congruent with

where the eye is attracted by a point of high information content (focal point), S's judge the stimulus as upside down. Some critics have attacked Hebb's physiology for being too speculative. Nevertheless, he has had an extremely stimulating effect on the study of perceptual development, especially by means of manipulation of early experience.

C. Neurophysiological Approach

Hebb's ideas are also relevant to the neurophysiological approach to perceptual development. Teuber and Rudel (1962) have summarized considerable evidence concerning the perceptual effects of brain damage at various ages. These data are based on such tests as location of embedded figures and on tests of localization under conditions of body tilt. The study documents quite forcefully the thesis that the perceptual effects of brain damage depend on the age of S at testing and on the type of perceptual activity being tested. For example, the constant error in setting a luminous line to vertical when the body is tilted increases with age, but it increases more for normal than for brain-damaged children. On the other hand, setting body position to vertical from an initially tilted position results in higher constant error (further toward tilt and away from true vertical) in brain-damaged children than in normal controls, but this difference decreases with age.

Buch and Lefford (1963, 1967) have presented an integrated theoretical view of perceptual-motor development based on evidence from brain damage and the evolution of behavior. From both neurophysiological and comparative evidence they suggest three hypotheses about the development of perceptual-motor behavior.

1. There is a developmental shift from control of movement by proximal stimulus input (e.g., proprioception) to teloreceptive systems (e.g., vision). This hypothesis seems to suggest that young infants initially are more responsive to touch, proprioception, and vestibular stimulation and that with age, behavior comes to be controlled by such systems as vision and audition. Teloreceptive control is well instituted by 5 years of age (Buch and Lefford, 1967, p. 8).

2. There is a development of integration of the various sense modalities and activity is

mediated by stimulation patterned from the several modalities. An example of this in infancy presented by Birch and Lefford is the fact that a rooting response can be elicited in the neonate by squeezing the ball of the thumb. However, within a few months this stimulus is no longer effective unless the arm is adducted at the shoulder and bent at the elbow; this means a patterning of tactual and proprioceptive stimulation is now necessary to elicit the response.

3. There is increased intrasensory differentiation as well as sensory integration. That is, there are changes in the aspects of stimulation within a single modality to which organisms respond. Such increased intrasensory differentiation was thought to be reflected in improvement in visual recognition of shapes, a task used in an investigation designed to evaluate the general position.

In this study ability to copy designs was correlated with performance in intersensory and intrasensory tasks. There was a strong association between intersensory performance and the perceptual-motor coordination required by the copying task. However, a positive association between intrasensory functioning and the copying task was found only with a variation of the copying task that involved ability to utilize supplementary visual cues. The age range of the children, 5 to 11 years, was already beyond the stage where there could be a test of the first hypothesis. However, it will be recalled that the related hypothesis that visual perception matures later than tactual has been called into question earlier in this chapter and elsewhere by the present authors (Pick, Pick, and Klein, 1967).

D. Conclusions

Birch and Lefford's third hypothesis of intrasensory differentiation is reminiscent of the theoretical points of view of Gibson and of Werner and Wapner. Is it possible to distinguish these various differentiation theories? Both Birch and Lefford and Werner and Wapner provide for increasing hierarchic integration along with increasing differentiation. This accounts for the obvious increase with age in ability to cope with complex aspects of the environment and in particular to respond in a similar way to stimuli which are functionally similar but physically very dif-

ferent Gibson, on the other hand, accounts for this ability with the same mechanism as before, differentiation. Complex or higher-order variables of stimulation are distinguished and response is made to these. It is in this sense that the properties of the stimulus are emphasized and changes in attention to them are important rather than changes in processing of the same stimulus properties. Gibson would accept the importance of categorization and other mediation processes in cognitive tasks rather than in tasks involving perceptual change.

The clearest distinction in the concept of differentiation as employed by Gibson and the others is in the range of problems addressed and in the specificity with which it is applied. Both Buch and Lefford and Werner and Wapner have applied the concept mainly to intrasensory problems, whereas Gibson has used it in the study of intersensory problems (grapheme-phoneme units) as well as in the study of depth and shape perception. She has also been more precise in specifying the stimulus dimensions that are differentiated.

The study of the development of shape perception has been undertaken from more of the theoretical points of view considered in this chapter than has any other single problem. The Gestalt, Gibson, Hebb, and Soviet motor-copy views have all been centrally concerned with this problem and some of the other views have been concerned with it insofar as they have studied illusions and embedded figures. The Gestalt influence has been noted in problem areas other than the direct study of shape perception. The investigation of individual difference variables of field dependence and field articulation, the widespread use of various embedded figure tests, and the importance placed on figure-ground relations in the study of brain-damaged children reflect the pervasiveness of some of the Gestalt concepts.

The development of depth perception has not been a focal problem for many of the theoretical positions. Gibson has investigated the problem and Brunswik has inferred the effect of early experience. Perception as a cognitive process has been emphasized in Piaget's and Pollack's investigations as well as in Brunswik's analysis of size and shape constancy. None of the theoretical positions is seen as dealing completely and carefully

with all of the problems of perceptual development. In fact only the Gestalt theorists, and Hebb, and Gibson even address themselves to more than one or two aspects of perceptual development. A comprehensive theory probably awaits the interrelating of many of the problems previously described, which heretofore have been investigated only in isolation.

A concluding question about perceptual development is whether there are any such dramatic qualitative age changes in perception as the development of the conservations in cognition. At this point there is certainly no solid evidence for such changes, with the possible exception of imprinting. As far as basic sensitivity is concerned, it appears that the age changes that occur are very gradual. If qualitative changes are to be found, they will probably occur in changes of attention with age or in changes in perceptual integration across sense modalities or across time delays, although even in these areas the evidence to date suggests gradual change.

The problems of attention and perceptual integration have been rediscovered and are arousing great interest. The mechanisms of attention and education of attention, however, are not even clearly defined concepts, much less well understood, and it seems likely that they will be crucial in any general theory of perceptual development. Furthermore, even very basic questions such as span of attention have not been investigated from a developmental point of view. Perceptual integration, which must comprise a large part of real-life perception, has received relatively little emphasis in research. Yet there are a number of remedial (reading problem, retardation, etc.) procedures based on the supposed importance of sensory-motor coordination (Kephart, 1960, Delacatto, 1963). Such procedures both emphasize the need for basic research on perceptual integration and hold out promise of great reward.

The study of perceptual development has usually drawn its problems from the traditional study of perception, as witness the amount of literature in this chapter on perception of size, distance, shape, illusions, etc. The field may well be beginning to draw its problems from the real world. The recent research on reading is an example of this. The social problems of cultural and environmen-

tal deprivation may set additional problems. For example, practitioners in special education are becoming increasingly aware of "perceptual" deficits, not only of the blind and deaf but also of the physically handicapped and of those with learning disabilities. Problems derived from the real world can have theoretical as well as practical significance. A more analytic approach to the problem of deprivation and enrichment, for example, might be suggested. Such an analysis could then be

integrated with the more analytic experimental approaches to the problem of deprivation recently undertaken by Hein and Held (1967). The results of such manipulations of early experience contrasted with the discovery of complex stimulus detectors (Hubel and Wiesel, 1962) and the suggestion of innate linguistic categories (e.g., McNeil, 1966) raise once again the initial question of this chapter, nativism versus empiricism, but it is at a new level of complexity.

12. *Learning in Children*

HAROLD W STEVENSON*

Research on children's learning is for the most part a derivative of psychological studies of learning in animals and human adults. Although the impetus for studying children's learning is related to practical concerns in the educating and rearing of children, the field characteristically has been dominated by the methods and problems of the experimental psychologist. The studies typically have been laboratory investigations, and until very recently few studies had been conducted in naturalistic or classroom settings. Child psychologists have not rejected other methods as being unsuitable or inappropriate, but they have tended to use the experimental method because of the ease with which problems originating in the experimental study of learning in animals and human adults could be adapted to the study of children. The close alliance with experimental psychology has been productive. The number and quality of studies on children's learning published each year have continued to increase. In many ways, however, the consequence of such an approach has been to provide more information about the general phenomenon of learning than about the distinctive characteristics of learning in the immature organism.

(The first studies of children's learning were straightforward adaptations of studies that had been conducted with animals. Among the earliest was Krasnogorski's (1909) study of the

development of conditioned responses in children. Krasnogorski, and somewhat later Ma-teer (1918), assessed the degree to which children's behavior, in this case salivation and chewing movements, could be modified by pairing conditioned and unconditioned stimuli. The success of these studies, and the seemingly general power of the conditioned response paradigm as a means of understanding behavioral change, led to the early promulgation by Watson (1928) of the conditioned response as the key to effective child training. Watson's defense of his position was not limited to discussions of the work of others, for some of the best known studies of children's learning were conducted in his laboratory (Jones, 1924a, 1924b, Watson and Raynor, 1920, Watson and Watson, 1921) on the instigation and elimination of children's fears by means of conditioning and extinction. As might be expected, Watson's espousal of learning as the primary source of behavioral change met with vigorous opposition, and arguments about the role of learning and maturation rocked the field for many years. In the end, Watson's major influence proved to be methodological rather than substantive. The strong behavioristic orientation of American studies of children's learning can be traced to Watson's emphasis on the objective study of behavior.

Partially as a response to the proponents of conditioning such as Watson, and partially as a result of the inherent importance of the topic, many early investigators were concerned with the acquisition of sensorimotor skills. A large proportion of the studies of sensorimotor learning were designed to answer the general question of whether a given amount of practice is equally effective, independent of the

* This paper was written while the author was in residence as a Fellow at the Center for Advanced Study in the Behavioral Sciences, supported in part by Special Fellowship (HD-35961) from the National Institute of Child Health and Human Development, U S Public Health Service

child's level of maturation. Of these studies, perhaps the best known are those of Gesell and Thompson (1929), Hilgard (1932), and McGraw (1935). In these studies there typically were two groups of children: an experimental group, which received intensive training on a particular skill over a period of time, and a control group, which was given infrequent or no practice for the same period, followed by intensive training. The importance of the interaction of learning and maturation was clearly demonstrated, for when young children were given relatively simple tasks, such as learning to climb stairs, to cut, or to button, increasing maturation resulted in increasingly greater effectiveness of a given amount of training. By the late 1930s, however, interest in sensorimotor learning had waned, and only minimal attention has been given to the topic for the past several decades.

The early research also included an array of studies on diverse topics whose only common feature was an interest in contrasting the performance of children with that of lower animals or human adults. Examples of such comparative studies are those on delayed reactions by Hunter (1913, 1917), on maze learning by Hicks and Carr (1912), and on the solution of puzzles by Lindley (1897). These studies, and indeed most of the early studies of children's learning, were characteristically problem oriented. They were concerned with such questions as whether children performed more effectively than lower animals, whether differences in CA, IQ, or sex resulted in differences in performance, and how the performance of children differed from that of adults. The empirical orientation of such studies is not surprising, for theoretical positions of some complexity did not begin to be formulated in discussions of the psychology of learning until the 1930s.

Many early studies were also concerned with the pragmatic questions of whether performance in learning tasks could be improved by the introduction of incentives and whether training was task-specific or transferred to other types of tasks. The demonstration by Thorndike (1932) of the facilitative effects of introducing rewards on the performance of animals and human adults led directly to investigations of whether similar effects would be found with children. Although there were differences in the relative effectiveness of dif-

ferent incentives when, for example, the performance of children was compared with that of adults, the results generally indicated a higher level of performance when the child was presented an incentive for correct response than when he was not (Abel, 1936; Hullock, 1931). Thorndike (1924) also stimulated an interest in transfer of training, but his work was preceded by that of such persons as Judd (1908) on the general effects of practice on rote memory. A typical study was that of McGinnis (1929), who investigated transfer in the stylus-maze learning of preschool children. A more exhaustive delineation of early studies of children's learning would include work on retention (e.g., Meek, 1925), forgetting (e.g., Ballard, 1913), and the effects of guidance on learning (e.g., Gates and Taylor, 1923; Goodenough and Brian, 1929). There were also many studies of problem solving, but this is the topic of another chapter in this book and the research will not be discussed here.

This early research accomplished little other than replicating the findings of earlier studies. Munn (1954, p. 449), in concluding his review of children's learning for the preceding edition of this *Manual*, summarized his impressions in the following way:

So far as discovering anything fundamentally new concerning the learning process, the investigations on learning in children have failed. One possible reason for this is that such investigations have from the first been patterned too much after the lines of earlier research with animals and adults in the laboratory. A more likely reason, however, is that the phenomenon of learning is fundamentally the same whether studied in the animal, child, or adult.

Although we may wish to qualify the second interpretation, Munn's general conclusion seems appropriate. Educational and child-rearing practices and other research in learning were not strongly influenced by the work that had been done with children. This does not mean, however, that teachers and parents were not influenced by psychological research in learning. Such research consistently has been a focus of attention in educational psychology and, especially in the heyday of conditioning, was an important source of advice

about how parents should rear their children. The overall similarity in the results of studies with children and those with other subjects was interpreted by many as indicating that the results of studies on animals and adults could be applied directly to the child, and because of this child psychologists often found it convenient to discuss children's behavior in terms of learning principles. This, in addition to the efficient and replicable procedures of laboratory studies, gave child psychology a learning and experimental orientation that still persists.

It would be unfortunate if the more recent research on children's learning had produced only a proliferation of adaptations and translations of research with animals and human adults, but this has not been the case. Although the studies still are intimately related to the general body of research in learning, investigators have begun to capitalize on the characteristics of children that make them especially suitable subjects for yielding new information about the learning process. Two of the most important characteristics are the developmental changes in the role of language in the control of behavior and the degree to which the child's behavior is influenced by that of other persons. It seems logical, and the studies have offered support for such an argument, that the learning process would undergo changes as the child gains linguistic competence and undergoes socialization experiences. Research became more productive and the study of children's learning was vitalized when psychologists began to select children as subjects because of their distinctive characteristics and not merely because of curiosity about how children would perform in standard laboratory tasks or because they were readily available and cooperative.

A second factor that transformed research with children from a replicative to an innovative field of investigation was the development of increasingly sophisticated theoretical models and systems in general psychology. None of these has been concerned explicitly with developmental processes, but they have been a valuable source of ideas and, importantly, have elucidated the possible importance of particular variables in determining how children learn. Because of these theoretical advances, current research with children is typically variable-oriented, in contrast to the

problem orientation of earlier studies. It would be an overstatement to say that all learning studies with children now seek to assess the significance of particular variables. Most commonly, however, questions are asked about how experimental variables influence learning either singly or in interaction, rather than questions such as how long it takes children to learn a certain task, whether performance differs according to age, sex, and intelligence, and how the performance of children differs from that of lower animals.

By now there have been so many studies of children's learning that it is impossible to review them adequately in one chapter. Fortunately, comprehensive reviews have appeared in the two previous editions of this book (Munn, 1946, 1954) and in the two editions of *A Handbook of Child Psychology* (Peterson, 1931, 1933). In addition, the recent rapid development of the field has led to the publication of numerous reviews of research on particular topics (Bijou and Baer, 1963, 1966, Cantor, 1965, Castaneda, 1965, Denny, 1964, Fowler, 1962, Gollin, 1965, House and Zeaman, 1963, Kendler, 1963, Lipman, 1963, Lipsitt, 1963, 1967, Long, 1959b, McPherson, 1948, 1958, O'Connor, 1958, Reese, 1963, Ross, 1963, Shepp and Turriss, 1966, Spiker, 1963, Stevenson, 1963, Terrell, 1965, White, 1963, Zeaman and House, 1967). It seems desirable therefore to concentrate in this review on the topics that currently are receiving the greatest amount of attention. References to earlier research are made only when such information is necessary to place a topic in its historical context. Some topics included in earlier chapters such as sensorimotor learning, memory, and problem solving are omitted, either because they have been inactive areas of research or because they are discussed in detail elsewhere in this book. Thus this chapter generally supplements, rather than reiterates, what has been discussed in previous general reviews.

This chapter begins with a consideration of the most simple form of learning, the conditioned response, and proceeds through a discussion of more complex forms. Although it would have been desirable to organize the chapter around variables that influence learning or around basic processes in learning, the most convenient and economical mode of organization appeared to be by type of task.

Because so many different tasks have been used, and because the tendency has been to investigate particular topics with a limited number of tasks, a large amount of repetition would have been necessary if another mode of organization had been used. Basic studies that have used normal children as the subjects receive primary attention, and studies dealing with special populations, such as the retarded, the deaf, and the disturbed, have not been discussed. Because of the vast number of publications no attempt is made to include all possibly relevant studies. The review is selective and discusses critical studies as intensively as possible. An attempt is made, however, to refer to reviews or other bibliographic sources for the use of persons who are interested in pursuing particular areas of research.

CONDITIONING WITH INFANTS AND YOUNG CHILDREN

Everyone who has had a course in introductory psychology is familiar with the basic facts about conditioning. Classical and operant conditioning, experimental extinction, spontaneous recovery, and the like have been demonstrated repeatedly with mature organisms from a wide variety of species. The initial interest in research with children was to ascertain whether these processes could be established in the human infant and child, and when an affirmative answer was reached, attention was directed to the questions of when the infant could be conditioned, what kinds of conditioned stimuli were effective, and the kinds of responses that could be conditioned. The effectiveness and simplicity of the conditioning methodology have led to many attempts at training and therapy, and a sizable proportion of the work with children has dealt with these problems.

Neonatal Conditioning

Psychoanalytic theory proposed that the early experiences of the infant have a profound importance for later personality development. One test of the validity of this proposition, as well as Watson's (1928) proposition concerning the universal applicability of conditioning procedures, is to determine whether the neonate can be conditioned. Unless the neonate can be conditioned, it is doubtful that other types of experiences could have enduring

psychological effects. It would seem the question could be answered readily, but at one point the problems seemed to be nearly insurmountable. The report by Wickens and Wickens (1940) placed the results of earlier studies in question because of the lack of appropriate controls. As if it were not difficult enough to obtain subjects who meet the requirements of a stringent experimental design, neonates are troublesome subjects with which to work, for they are often asleep, irritable, or hungry.

Even more distressing than the inadequacies of the earlier studies were the actual results of the Wickens' investigation. During a series of training trials, neonates in an experimental group were presented the sound of a buzzer as the conditioned stimulus and a shock to the foot as the unconditioned stimulus, in one control group the neonates were presented only the buzzer and in another only the shock. Clear evidence of conditioning was found for the experimental group, but similar results also were found for the group that had been presented only the shock during the training trials. One of the interpretations of these results was that the effective conditioned stimulus for both of these groups was a change in the stimulus complex and that as the shock had constituted such a change in the training period for the control group, the buzzer constituted such a change in the test trials and therefore was capable of eliciting the conditioned response of leg retraction. If this were the case, and neonates were so sensitive that any change in the environment might operate as a conditioned stimulus, it seemed unlikely that a study could be designed to assess the critical features of the conditioned response.

Following the Wickens' study, interest in the problem was dormant until new techniques were introduced in the mid-fifties. The Wickens' somewhat incongruous results turned out to be partly attributable to their use of electric shock as the unconditioned stimulus. Shock and other aversive stimuli, except, perhaps, so mild a stimulus as a puff of air to the eye (Lantz, Fitzgerald, and Brackbill, 1967), have the undesirable effect of heightening the organism's level of arousal and thereby altering threshold values for response. Such effects seem to occur with less frequency when the stimuli are non-noxious, and studies of appetitional conditioning have given much more clear-cut demonstrations of neonatal condi-

tioning than had previously been available. The most notable work has been that of Papoušek at the Institute for the Care of Mother and Child in Prague.

Papoušek was fortunate in having infants available at the Institute from birth through the first six months of life. Thus he could begin his studies with infants of different ages and proceed through a series of conditioning, extinction, reconditioning, discrimination, and reversal procedures. Summaries of his work have appeared in several recent publications (Papoušek, 1965, 1967a, 1967b). Following is the basic procedure used in these studies.

The UCS (milk) was presented by the assistant, who sat screened behind S's head. If S responded to the bell and turned to the left, milk was offered to him immediately. The bell continued to ring until S started sucking the milk. If S did not respond to the presentation of the CS within 10 seconds, the assistant (nurse) tried eliciting the head turn by tactile stimulation, touching the left corner of his mouth with the nipple. If this stimulation was ineffective, she turned his head to the left and placed the nipple in his mouth. At the end of reinforcement the nurse turned his head back to the middle, leading it with the nipple, and then took the nipple from his mouth (Papoušek, 1967b, p. 255).

Ten such trials were given each day until five consecutive positive responses were made in a daily session. In the basic study, conditioning was begun with groups of infants with mean ages of 3, 86, and 142 days.

In the youngest group an average of 32.2 trials was necessary before the first conditioned head-turn appeared, and the average number of trials required to reach criterion was 177. Thus conditioning was demonstrated during the neonatal period and in some cases was quite rapid. Criterion was reached within 7 days by some infants, but others required more than a month of training. Generally, the rate of conditioning of newborns was slow in comparison to that of the two older groups of infants, who required an average of only 42.3 and 27.8 trials, respectively, to reach criterion.

Papoušek (1967b) discerned several stages through which the infants passed prior to the formation of stable conditioned responses. During the first phase, the CS elicited non-

specific orientational behavior, then partial responses, and finally the first conditioned responses. This phase was relatively long in neonates and included signs of distress. The next phase was unstable conditioning, which in neonates sometimes included generalized movement of the whole body. Ultimately a phase of stable conditioning was reached in which the responses were stronger, faster, and made with signs of pleasure rather than distress.

A closely related study has been reported by Siqueland and Lipsitt (1966). Two groups of infants between 1 and 2 days of age were presented 30 trials in which a buzzer preceded tactile stimulation of the cheek by 2 seconds. One group was reinforced with a dextrose solution immediately following rotation of the head to the side of stimulation, whereas in the other group reinforcement occurred 8 to 10 seconds after termination of the tactile stimulus. After training, the Ss received 12 extinction trials. The results reflected significant effects of the reinforcement and extinction procedures in the experimental group and a relatively stable level of response across trials in the control group. Two aspects of the study yielded negative findings. Amount of deprivation did not influence the rate of conditioning, for there were no significant differences in performance of the Ss, with half of each group tested 1 hour after feeding and the others tested 2½ hours after feeding. Further, there was no reliable indication of conditioning with the measure used by Papoušek, for the Ss showed no significant tendency to anticipate the presentation of the UCS by rotating their heads following the onset of the buzzer.

Siqueland and Lipsitt (1966) applied the same basic procedure in studying learned differentiation of stimuli by neonates and the reversal of responses to positive and negative stimuli. In the first study, 1- to 5-day-old infants were presented 48 trials in which tactile stimuli, preceded by distinctive sounds, were presented alternately to the left and right cheeks. Response to one of the stimuli was reinforced and response to the other was not. The frequency of head-turns to the reinforced side increased significantly over trials, whereas there was no increase in the frequency of response to the nonreinforced side. A habituation effect was demonstrated in the control Ss for whom reinforcement was not contingent

upon head-turning. With another group of 2- to 5-day-old infants head-turns preceded by one auditory stimulus were reinforced and those by another were not. After 60 acquisition trials the pattern of reinforcement was reversed for a second series of 60 trials. Clear evidence of the infants' ability to discriminate auditory stimuli was found, not only did the frequency of responses to the positive increase during training, but by the end of the reversal trials the frequency of response to the previously negative stimulus exceeded that to the previously positive (now negative) stimulus. The results of a study by Lipsitt, Kaye, and Bosack (1966) indicated that the effects found in the latter studies were not limited to the head-turning response. When the insertion of a rubber tube in the mouths of 1- to 4-day-old infants was followed by reinforcement with a dextrose solution the rate of sucking increased significantly, and when the reinforcement was omitted the rate dropped to a baseline level. Rate of sucking therefore was significantly altered by the reinforcement contingencies.)

Further evidence of the modifiability of neonatal behavior has been reported by Kaye (1965) in a study of the Babkin reflex. In this reflex pressure to the palms of a supine infant results in the infant's opening its mouth. The arms of 2- to 4-day-old infants were moved from the extended to the flexed position and pressure was applied to the palms when the arms were in the flexed position. In tests following 35 training trials, the frequency of mouth opening to arm movement alone was significantly higher than that which had been found in a baseline period and was consistently above that of control Ss for whom arm movement had not preceded pressure to the palm during the training trials.

Other recent studies of neonatal conditioning have been discussed by Brackbill and Koltsova (1968), Lipsitt (1963), and Papoušek (1967a). Among the most notable of the studies offering evidence of conditioning are those by Dashkovskaia (1953) on conditioning of the eye-blink reflex in 8-day-old infants and by Krachkovskaia (1967). In the second study an increase in leukocyte count, which typically occurs in infants following feeding, was found in 8-day-old infants at the time they usually were fed when the feeding was omitted to allow testing without food. A simi-

lar form of temporal conditioning had been reported earlier by Marquis (1941), who found an increase in bodily activity after the third hour in 9-day-old infants whose feeding was altered from a 3- to a 4-hour schedule. Considering all these studies, there seems to be little question that neonatal conditioning is possible.

The next obvious question is whether conditioning is possible prior to birth and in infants who are born prematurely. The best known study of prenatal conditioning is that of Speltz (1948), who reported what appeared to be conditioning of the fetus *in utero* during the last two months of gestation. Unfortunately, this study has not been followed by further research, and in the face of the inadequacies of the controls, especially of the mothers' perception of the UCS and the CS, it is difficult to conclude that successful conditioning was demonstrated. Premature infants apparently can be conditioned, but this problem, too, will require additional research before satisfactory conclusions can be drawn. Other than the disrupting effects that might occur from the greater incidence of physical anomalies in the premature, there would be no reason to expect that premature infants would be less susceptible to conditioning than would full-term babies, if both are tested at comparable gestational ages. When groups of prematures were matched with full-term infants on the basis of time since delivery, Janoš (1965) found slower conditioning in the prematures, but they were nevertheless able to reach a criterion of five consecutive eye-blinks to a tone. The argument has been made that the greater opportunities premature infants have for stimulation may result in faster conditioning, but at present there is no evidence that prematurity is especially advantageous to learning.)

Habituation

The status of habituation is still being debated, some regard it as an example of learning, whereas others view it as the result of more basic neural processes (see Bartoshuk, 1962). At any rate, the diminution of response to repetitive stimulation illustrates a change in behavior as a function of repeated experience with a particular stimulus, a definition that often is used for learning. The process has been demonstrated in lower animals, neonates, and

older infants. Recent interest in the study of habituation with neonates is attributable to a study reported by Bronshteyn, Antonova, Kamenetskaya, Luppova, and Sytova (1958), in which a tone or odor followed the insertion of a pacifier in an infant's mouth. Initially, the infant ceased sucking when the odor or tone was presented, but with repeated presentations the stimulus became ineffective in suppressing sucking. A repetition of the study by Keen (1964) produced less striking results than those reported by Bronshteyn et al., when the duration of the tone and intertrial interval were carefully controlled; there was less cessation of sucking to the tone than had been found in the earlier study. Also, habituation occurred much more slowly, and there was no evidence that the neonates discriminated between the two tones (400 versus 4000 cps) that were used. The inexplicitness of the Russian report makes it impossible to assess the basis for these discrepancies in results. Keen did find, as had Bridger (1961) in a study of cardiac acceleration to tones, that the duration of the stimulus played a more important role in producing habituation in neonates than did the interval between presentations. Other efforts (Kaye and Lavin, 1963; Solomons, Hardy, and Melrose, 1965) have been unable to produce habituation of the sucking response.

Two other studies using olfactory stimuli and body movement as the response have found evidence of habituation (Engen and Lipsitt, 1965; Engen, Kaye, and Lipsitt, 1963). The percentage of neonatal responses to the stimulus (anise or asafetida) decreased with repetitive stimulation and the effect of previous experience generalized, for more rapid habituation was found to each odor when it was presented after habituation had occurred to the other. When two odors (amyl acetate and heptanal) were combined habituation to the mixture occurred, and when the odors were presented singly there was recovery of the habituated response.

Conditioning in Older Infants

In contrast to the small number of studies that have been conducted with neonates, there have been many studies of conditioning with older infants and children. Soviet psychologists and physiologists, trained in the Pavlovian school, have been responsible for a large proportion of this work. Reviews of the most sig-

nificant of these studies have been presented by Brackbill (1962) and Brackbill and Koltsova (1968). Despite the extensive work that has been done, a great deal of parametric work still is needed. Little is known, for example, about the effects of length of presentation of the CS and UCS, the interval between presentation of CS and UCS, the intensity of the CS, and reinforcement mechanisms in conditioning the young human being.

The Soviet work has been multifaceted, but two consistent lines of investigation have been studies of the effects of the CS on conditioning and of the development of higher-order and complex forms of conditioning. According to Brackbill (1962, p. 110), "Soviet physiologists maintain that in conditioning—at least in classical conditioning—there is only one really influential member of the triad, CS-UCS-CR, and that is the first member." Accordingly, much time has been spent in ascertaining developmental trends in conditioning as a function of the type of CS used. All types of stimuli have not been found to be equally effective at all ages, for maturational changes in the sensory apparatus appear to result in a developmental sequence in the relative effectiveness of a particular CS. This sequence, according to Kasatkin (Brackbill and Koltsova, 1968), is such that vestibular stimuli are effective earliest, followed by auditory, tactile, olfactory, taste, and visual stimuli, in that order. There are problems, of course, in equating the intensity of stimuli differing on qualitative dimensions, but for the present there is little evidence that this sequence is not correct.

Soviet investigators distinguish three categories of stimuli as being effective in eliciting responses in the human being. Unconditioned stimuli elicit reflexive responses, conditioned stimuli become capable of eliciting such responses through their association with unconditioned stimuli, and, at a later developmental level, words develop meanings that, if associated with the CS, become capable of eliciting the conditioned response. Conditioned stimuli constitute what are called the first signal system and words constitute the second signal system. A great deal of emphasis has been placed on the role of the second signal system in the development and control of human behavior. A study by Degtiar (1962, cited by Brackbill and Koltsova, 1968) illus-

tates the type of research that has been done on the emergence of the second signal system. Children from 1½ to 3 years of age readily developed conditioned responses to visual and auditory stimuli which generalized to the verbal cues "lamp" and "bell." The youngest Ss were incapable of generalizing the response to abstract designations of these stimuli and did not respond to the words "light" and "sound," even though they had been taught the meaning of these words before participating in the experiment.

A second example of studies of the second signal system is that of Koltsova (1967) on the role of excitation and inhibition in the development of generalization. In an initial experiment there were two groups of 2-year-old Ss. In the first group the presentation of geometrical figures was accompanied by a puff of air to the eye and the utterance "thing," whereas the presentation of objects such as a key or drumstick was never accompanied by the puff or the word. In the second group the presentation of small skeins of yarn was always followed by an air puff, but only those in which yellow predominated were accompanied by the word "thing." Stable discrimination between the positive and negative stimuli was found in the first group as successive stimuli were presented, but in the second group successive presentations of the same or different skeins resulted in increasingly weak and unstable responses and, eventually, extinction. When the children were asked to pick out a "thing" from sets of objects, clear differentiation was found in the first group, for the Ss always chose geometrical forms, but in the second group the Ss chose only the brightest and largest of the objects. The results of this and subsequent similar studies were interpreted as evidence of the necessity for developing inhibitory as well as excitatory processes before successful generalization from earlier conditioning can occur.

Many other examples of Soviet research could be cited, such as studies of auditory discrimination, color vision, and the conditioning of physiological responses, but most of these studies deal with capacity rather than process. Perhaps the major impact of these studies has been the demonstration of the ubiquity of the conditioning process. Conditioning has been shown to be an important tool for assessing the abilities of the preverbal child,

the functions of language, the operation of physiological processes, and the possibilities for remediation of defects or deficits in behavior.

The most noteworthy non-Soviet study of conditioning of older infants and young children is that by Papoušek (1967b). As indicated earlier, Papoušek found developmental changes in the rate with which head-turning could be conditioned. In rate of extinction, however, the three groups of Ss, now 32, 94, and 149 days of age, all met the criterion of five consecutive negative responses in approximately the same number of trials (25 to 27). The latency of the CR was longer for the youngest group, and for these Ss there was a significant correlation between trials to condition and trials to extinguish, but otherwise there was no basis for interpreting the remarkable similarity in rate of extinction among the three groups of Ss. Reconditioning occurred no more rapidly than original learning for the two oldest groups of Ss, but it was faster for the youngest group. Age differences also were found for speed of discrimination involving reinforcement of responses to a bell on the left and to a buzzer on the right, and for reversal of this discrimination. This same negative relation between age and number of trials to criterion has been reported in at least 13 other studies of conditioning (Blackbill and Koltsova, 1968).

The studies reviewed thus far have not been separated into those using classical conditioning procedures and those using instrumental or operant procedures. The distinction between those in which behavior is elicited (classical) and those in which behavior is emitted (operant) is of importance, however, in introducing the next group of studies, which are all the operant type. The operant method has been popularized by Skinner and his students, but the initial systematic studies of operant conditioning with children were conducted by Ivanov-Smolensky (1927). In Ivanov-Smolensky's studies, which have been reviewed by Razian (1933), the child was able to release a piece of food from a container by pressing a rubber bulb. The CS (bell or light) was presented just before the food was visible. Such a technique was effective in establishing stable conditioning, higher-order conditioning, and conditioning to chains of stimuli with young children.

Rheingold, Gewirtz, and Ross (1959) capitalized on the usefulness of operant techniques in their study of the conditioning of vocalization in the 3-month-old infant. Vocalizations were reinforced by a complex of social acts, including smiling, making "tssk" sounds, and touching the baby's abdomen. Such acts were effective in increasing the frequency of vocalization over that found in a baseline period and, when omitted, in reducing the frequency of vocalization to approximately the baseline level. The experiment was conducted in 9 daily 3-minute sessions over 6 days. The results appear to offer clear evidence of conditioning, but an alternative interpretation of the increase and subsequent decrease in vocalization is possible. The social stimuli may have had an arousing rather than a reinforcing function. The validity of such an interpretation was investigated by Weisberg (1963), who replicated the experimental conditions of the Rheingold et al. study adding groups for whom vocalization was reinforced by a non-social stimulus (door chime), groups in which either the social or nonsocial stimuli were not contingent upon S's vocalizing, and nonreinforced groups in which the adult was present and in which the adult was absent. Successful conditioning and extinction were found in the first group only, thereby supporting the conclusion that conditioning had been demonstrated in the earlier study.

Two other studies offer evidence of operant control of infants' social behavior. The frequency of smiling in 4-month-old infants increased significantly when an adult reinforced smiling by picking up the baby, smiling, and talking to him (Blackbill, 1958). Evidence of extinction, accompanied by an increase in protest responses, was found when reinforcement was discontinued. (The presence of such emotional responses during extinction was also noted by Rheingold et al.) Etzel and Gewirtz (1967) also used social stimuli to reinforce smiling in 6- and 20-week-old infants while simultaneously attempting to reduce the incidence of crying by nonreinforcement. These studies demonstrate with infants what will be abundantly clear in later discussions of research with older children. The adult may exert powerful control over behavior by following desired responses with reinforcement and by withholding reinforcement following undesired responses.

CONDITIONING STUDIES WITH OLDER CHILDREN

Studies of conditioning with older children have relied nearly solely on operant methods. The degree to which operant conditioning has captured attention is exemplified in the recent books on child development by Bijou and Baer (1961, 1965), where the principles of operant conditioning provide the guiding theme in their analysis of behavior. The basic tenets of such an approach have been summarized by these writers:

The positivistic approach is usually functional: an area of behavior is defined and then procedures are established to discover those variables which control it. As discoveries are made, responses are described as functions of certain experimental manipulations, usually of stimulus events in the past and present environments, and a set of empirical laws evolves. Concepts arise not because of their imaginative, logical, or global characteristics, but only as they serve to describe and summarize the experimental stimulus operations which control behavior. Hence, such concepts are functional in that they pertain only to those procedures demonstrated to influence the behavior in question (Bijou and Baer, 1966, p. 719).

The basic principles of operant conditioning are simple, explicit, and applicable to a wide variety of behavior. (Initially research was concerned with problems such as the kinds of response that could be modified, the classes of stimuli that were effective reinforcers, and the types of schedule of reinforcement that were optimally effective.) (e.g., Baer, 1960, 1961, Bijou, 1957, 1958, Bijou and Stuijges, 1959, Long, 1959a). The catalogist function has not dominated such research, however, and the principles have been investigated in a number of novel and interesting ways.

Verbal Conditioning

(The verbal behavior of children, at least within the restricted settings that have been used, can be effectively controlled by making reinforcement contingent upon the emission of a particular verbal response. Of special interest has been the analysis of the relation of situational and antecedent conditions to children's conditionability. A good example is the

developmental study by Baer and Goldfarb (1962) in which Ss in grades 3, 6, and 10 were asked to select a pronoun from a list and use it as the first word in a sentence. The experimenter (a male adult) made a supportive comment after each sentence that began with "I." Developmental changes in rate of conditioning differed for boys and girls. The greatest increment in "I" responses occurred for grade 3 boys and grade 10 girls, and the smallest increments for grade 3 girls and grade 10 boys. Sex differences were small at grade 6. The tendency, then, was for the conditioning procedure to be increasingly effective with girls and decreasingly effective with boys as age increased.

Rowley and Keller (1962) employed the same procedure with 9- to 12-year-olds, but they added a control group that received no reinforcement and a second experimental group whose reinforcement consisted of a nod of the head and a smile from the experimenter. Performance did not change across trials for the control Ss, but there was a moderate increase in the number of reinforced pronouns with physical reinforcement and a marked increase with verbal reinforcement. Boys and girls performed at approximately the same level and there were no differences in performance between groups scoring high and low on a test of manifest anxiety.

The degree to which preschool boys could be conditioned to answer "Mother" or "Father" to a series of simple questions about a family of four dolls was found to differ by Epstein and Liveant (1963), depending upon boys' sex-role identification. The Ss were obtained by selecting the highest and lowest scorers from a large sample of boys given a test of sex-role preferences. Conditioning occurred in all groups, but boys who were classified as high-masculine identifiers were more effectively conditioned by a male than by a female experimenter. The male experimenter was a more effective agent of reinforcement for the high- than for the low-masculine identifiers, and the only group in which "Father" was not more effectively conditioned than "Mother" was the low-masculine group tested by a male.

Reinforcement in the preceding studies involved a social response from the experimenter. Would verbal conditioning also occur if a nonsocial reinforcement were used? A study by Erickson (1962) indicated that it

would not. Sixth graders were reinforced with the automatic delivery of a marble or with the statement "Good" each time they verbalized the name of the animate object in pairs of animate and inanimate objects. Prior to this task the Ss spent 15 minutes working on a game in which they were praised by the experimenter or performed alone. Conditioning occurred with verbal reinforcement when there had been no social interaction in pretraining, but even this form of reinforcement was ineffective when the Ss had been praised in their pre-experimental sessions.

These studies illustrate how radically the experimental situation changes when the experimenter enters the scene. The sex of the subject, sex of the experimenter, sex-role preferences, and previous opportunities for social interaction, all seemingly strange variables to consider in studies of conditioning, became important determinants of how rapidly learning will occur. Much more will be said about such variables in later sections.

Drive Level

There has been a great deal of interest in the effects of high levels of drive on the conditioning of instrumental motor responses. (Total drive level has been varied by increasing frustration,) by using incentives of different value, and by selecting Ss differing in level of anxiety.)

The impetus for using frustration comes from the hypothesis that nonreward in the context of reinforced trials leads to frustration, which increases drive, which, in turn, increases level of performance in situations employing simple, noncompetitive responses. One of the first investigations of this hypothesis with children was reported by Holton (1961). Preschool Ss were divided into three groups on the basis of pretraining experiences. Two groups received a large number of reinforcements (marbles) prior to receiving nonreward. In one of these groups, only a few more marbles were needed to reach the goal of filling a marble board that could be traded for a prize. A larger number of marbles was needed in the other group. A third group received a smaller number of reinforcements prior to nonreinforcement and needed only a small number of marbles to fill the marble board. The response measure

was force exerted on a panel whose depression resulted in the delivery of a reward. The amount of force increased in all groups between the early reinforced period and the period following the introduction of nonreinforcement. The increase was greater when nonreinforcement occurred near the goal and followed a large number of reinforcements or when nonreinforcement occurred further from the goal. (The effects of nonreinforcement therefore depended on both the prior number of reinforced trials and how close S was to reaching the defined goal.)

Endsley (1966) tested 7- and 8-year-olds in a related study. The Ss' efforts in an initial task met with either success or failure. To have another try at the first task, the Ss were required to push a button on a second piece of apparatus. The first task was rigged so that the Ss could be made to fail either near or far from the defined goal. In contrast to Holton's findings, both near- and far-failure Ss responded faster after success than after failure. The total situation, however, was much more complex, and it is likely that failure elicited avoidance responses, such as looking back at the apparatus of the first task, which interfered with the Ss' subsequent response on the second task.

Frustration effects may also be operative under conditions of partial reinforcement, where the same response may, depending upon the schedule, terminate either in reinforcement or nonreinforcement. Several studies have used a lever-pulling task to investigate this problem. At the onset of a signal S is required to pull a lever through its full excursion to terminate the signal or to receive a marble reward. Two measures of response, starting and movement speeds, are commonly used, but since starting speed has proved to be less productive in most studies, only results obtained with movement speed will be discussed.

Bruning (1964) and Ryan and Moffitt (1966) have found that movement speeds were faster with 50% than with 100% reinforcement. Incentive level was also varied in these studies, but only in the Ryan and Moffitt study were significant incentive effects obtained—and these were in the direction opposite from that predicted. (Groups working for incentives of low value increased their speeds, and the high-incentive groups showed

little change after an early, low asymptotic level of response.) This inversion may be readily explained by the fact that all Ss were aware of the two incentives, a piece of string and a toy. It is not unlikely that working for a piece of string became increasingly frustrating when the Ss knew that other children were being rewarded with a toy.

A more elaborate study by Ryan (1966) included six schedules of reinforcement. (Preschool children had faster movement speeds with partial than with consistent reinforcement. There was an orderly increase in the speeds as the percentage of reinforcement decreased between 100, 83, 66, and 50%, but the speeds decreased somewhat as the percentage of reinforcement decreased from 50 to 33 and 17%. These findings suggest an inverted U-shaped relation between asymptotic response speed and reward schedule. A subsequent study by Ryan and Voorhoeve (1966) replicated this effect.) Response speeds of 5-year-olds increased as the percentage of reinforcement for lever-pulling decreased from 100 to 70 and 50%, but decreased again as the percentage of reinforcement dropped to 30 and 10%. The facilitation of response with partial reinforcement thus begins to be lessened as the likelihood of nonreinforcement exceeds that of reinforcement.

Two-level tasks have also been used. Here, variation in percentage of reinforcement followed movement of the first lever, with movement of the second lever resulting in consistent reinforcement. Penney (1960) found that the movement speeds on a second lever were faster following nonreinforcement than following reinforcement on the first lever. Ryan (1965) replicated this effect in between-group comparisons where one group received 50% reinforcement on the first lever and the second group received 100%. The Ss worked either for a preferred or a nonpreferred incentive, but incentive level had no significant effect on movement speeds.

All of the preceding studies used tangible reinforcers. Ryan and Watson (1966) asked whether the same effects would be found with verbal reinforcement. When lever-pulling terminated in a supportive statement from the experimenter 33% of the time, movement speed increased as training progressed, but the speed changed only slightly

when Ss were given 100% reinforcement. The effects, then, were not limited to the use of tangible reinforcement.

The conclusions from these studies are consistent with partial reinforcement results in faster responding than does continuous reinforcement, but incentive is not an effective variable in itself in influencing rate of response. The studies provide supportive evidence for a frustration or drive theory, but, as several of the investigators pointed out, the results may also be predicted from an associational framework if it is assumed that the Ss may have learned from everyday experience that they should try harder in the face of low success. When there is only partial success in the lever-pulling task, the Ss may apply this dictum and increase their efforts in the only available way by pulling the lever faster.

Finally, there are the studies on anxiety. Anxiety is assumed by some theorists to act as an irrelevant drive, energizing all existing habits. In the lever-pulling task, which involves a well-learned response, highly anxious children should have faster response speeds than children with lower levels of anxiety. Penney and McCann (1962) tested groups of third and fourth graders who received high and low scores on an anxiety questionnaire. An escape conditioning procedure was used, where movement of the lever terminated a loud, unpleasant tone. The high anxious Ss had faster response speeds than low anxious Ss. If anxiety is an enduring characteristic of the individual, prior adaptation to a noxious stimulus should have less effect in altering the total drive level of high anxious than of low anxious Ss. To test this possibility, Penney and Kuwin (1965) exposed half of their high and low anxious fourth and fifth graders to a series of trials with an intense tone. The Ss then were tested in the lever-pulling task, where response terminated the previously experienced tone. There was no significant difference in the response times of adapted and nonadapted high anxious Ss, but adapted low anxious Ss had significantly slower response times than their nonadapted counterparts. Thus adaptation appeared to have reduced the total motivational level of the low anxious but not of the high anxious Ss.

The general conclusion from these studies is straightforward. When response involves a

well-learned habit such as lever-pulling, an increase in drive results in more efficient response. The effects appear to be similar whether drive level is increased by introducing frustration, by using a high level of incentive, or by selecting anxious children as Ss. As will be seen in later sections, these variables have a disruptive rather than a facilitative effect on performance when the correct response is initially weak in strength or when it is subject to interference from incorrect responses of higher strength.

Delay of Reward

A delay in the delivery of a reward in the conditioning of an instrumental response should, according to an associational interpretation, result in slower rates of response. According to this position, a delay increases the possibility that competing responses that are incompatible with the instrumental response will be conditioned. Further, the degree of interference should be a function of the similarity between the cues present during the delay period and those that elicit the instrumental response. Maximal similarity would occur if the stimulus situation did not change between the time of the onset of the cue and the delivery of the reward.

Rieber (1961a) tested these predictions with kindergarten children in a lever-pulling task. The excursion of the lever terminated in either immediate or a 12-second delay in reinforcement. In the delayed reinforcement groups the initiating signal (a light) remained visible during the delay period for half of the Ss and terminated with Ss' response for the other half. In line with the predictions, starting speed (i.e., the time between onset of signal and beginning of response) was fastest with immediate reinforcement and slowest when the signal remained on during the delay interval. Movement speeds revealed no difference between immediate and delayed reinforcement with immediate offset of the signal, but the speeds were slower when the signal remained on during the delay interval. It therefore appears that competing responses, presumably conditioned to the signal, had a greater differential effect on starting than on movement speeds. A more elaborate study by Rabinowitz (1966) confirmed Rieber's findings and added the information that the immediate delivery of tangible reinforcement in-

creased movement speeds over those found when such reinforcement was absent, that delay of signal offset affected movement speeds, and that delay of delivery of the reinforcer affected starting speeds

An additional study (Rieber, 1961b) included four groups of 6-year-olds who received either immediate or delayed reinforcement through 30 trials or were switched at trial 16 from one to the other condition. Starting speed proved to be the more sensitive measure. Immediate reinforcement resulted in faster speeds than delayed reinforcement when the conditions remained the same for all trials. Persisting effects of delayed reinforcement were evident in the second half of the trials, for among Ss who were switched to immediate reinforcement, starting speeds were slower than they were for Ss who received immediate reinforcement on all trials. Correspondingly, Ss who were switched from immediate to delayed reinforcement showed a marked decrease in their speeds during the second half of the trials

A study by Rieber and Johnson (1964) attempted to determine whether children could learn to anticipate reward conditions and vary their responses accordingly. The task involved alternating trials of immediate and delayed reinforcement. Additional cues (lights) were provided to signal the type of trial that would occur. In contrast to the previous results, response speeds were faster on the trials with delayed reinforcement than they were on the immediately reinforced trials, and the effect appeared with delays of 4, 8, and 16 seconds. Response speeds of all three groups were slower, however, than they were for a group of Ss that received consistent immediate reinforcement. Although the writers postulated that anticipation would be reflected in faster responding on immediately reinforced trials, the reverse argument can be made. The Ss may have learned to anticipate delayed reinforcement, and since anticipation of delay was frustrating, the speed of response increased. In this type of design, however, it is impossible to determine whether the differences are due to the residual effects of what occurred on the preceding trial or to the conditions prevailing on a particular trial.

Two other studies of the effects of delay on instrumental conditioning have been reported. Penney (1967) found response speeds in lever-

pulling to escape a loud tone were faster with immediate than with delayed reinforcement. Groups receiving alternating and random delayed and immediate reinforcement were included in the study. The insertion of immediately reinforced trials on an alternating schedule with delayed reinforcement did not change performance from that which occurred when all trials involved a delay of reinforcement, but somewhat faster speeds of response were found when the delay occurred randomly across trials. Harris (1967) found no difference in speeds of response when the delay of reinforcement was constant and when it varied between two values. Of greater importance, however, was the finding that an enriched surround (the presence of a large variety of interesting toys) did not produce significantly lower response times than did a stimulus-poor surround, even though the opportunities for developing competing responses would seemingly be greater in the enriched surround.

The results are consistent in indicating a disrupting effect of delayed reinforcement on speed of response in the instrumental conditioning of a motor response such as lever-pulling. Support for an associational interpretation of the effect would appear to be somewhat weakened by Harris' findings, but there is no indication that motivational or other interpretations offer a more powerful means of explaining the results.

Stimulus Familiarization

It has been suggested in the literature that the effectiveness of a conditioned stimulus decreases as the S becomes increasingly familiar with it. A series of studies has explored this problem in the instrumental conditioning of young children by exposing the Ss to the CS for a series of trials prior to commencing the conditioning procedure. Cantor and Cantor (1964) presented a buzzer or a light to kindergarten Ss for 40 2-second exposures before introducing the Ss to a lever-pulling task in which both light and buzzer served as conditioned stimuli. Starting speeds were markedly faster for the novel than for the familiar stimulus when the familiar stimulus was a buzzer, but only slight differences were found when the familiar stimulus was a light. In this, and in the subsequent studies, speed of response decreased across trials for both types of stimuli.

In a second study (Cantor and Cantor,

1965) Ss were given 40 3-second exposures to a red or green light. The experimental task was modified so that Ss were required to press a button of a color corresponding to that of the light. Response speeds were faster for the novel than for the familiar stimulus. A trial-by-trial analysis indicated that the fastest speeds occurred when a novel stimulus followed a familiar stimulus and the slowest speeds when a familiar stimulus followed itself. The magnitude of the effect thus appeared to depend on whether or not the preceding trial involved a familiar stimulus.

The same apparatus and procedure were used in a third study (Cantor and Cantor, 1966), but the number of familiarization trials was varied. Kindergarten Ss were given either 5 or 35 exposures to one of the two lights, the total number of preliminary trials was held constant by using a third, irrelevant light. Although response times were faster to the novel than to the familiar stimuli, 5 exposures were as effective as 35 in reducing speed of response—a somewhat incongruous finding. Another effect of novelty appeared in an analysis of individual trials: response times were faster when there was a change in the stimulus than when the same stimulus was repeated.

The stimulus familiarization effect obviously is replicable, but what is the underlying mechanism? Several alternative interpretations have been offered, including (1) a prolonged attention response is conditioned during the familiarization trials that interferes with rapid responding in the motor task, (2) familiarization trials induce habituation that reduces the subsequent effectiveness of the stimulus in eliciting attending responses, and (3) novelty is surprising and may produce an increased level of drive or heightened orientation that facilitates the execution of the motor response. Studies exploring these hypotheses have not been exhaustive, but at this time habituation seems to be the most satisfactory explanatory mechanism.

In a study by Witte (1967) the stimulus was presented 20 times during the familiarization trials, but the length of exposure was 4.5 seconds for half of the Ss and 1.5 seconds for the other half. Starting speeds of preschool Ss in a lever-pulling task were faster to the stimulus that had been presented with the shorter exposure times, thus giving some support to the habituation hypothesis. A method-

ological innovation was introduced by Bogartz and Witte (1966) which was relevant to the evaluation of the various hypotheses. The Ss were required to remove their finger from the button with stimulus onset during both the familiarization and conditioning trials. This procedure was adopted to decrease the possibility that competing responses could be conditioned during the familiarization trials. Again, however, kindergarten Ss showed faster response speeds to the novel than to the familiarized stimulus, a result that is hard to incorporate into a competing-response interpretation of the familiarization effect. Evidence against a surprise interpretation also was obtained. The authors noted that in prior studies the sequence of trials had been constructed, inadvertently, so that on 75% of the trials the stimulus was opposite to that presented on the previous trial. Such a sequence would be likely to produce an alternation pattern of responding, with faster responding on alternation than on repetitive response. Schedules therefore were constructed that involved 75% alternation-25% repetition or 75% repetition-25% alternation of response. The Ss in the first group responded faster on changed than on unchanged trials, whereas Ss in the latter groups responded faster on unchanged than on changed trials. The change effect therefore seems to be due to the structure of the schedules rather than to novelty. Thus only the habituation hypothesis appears not to have been discredited. A habituation hypothesis has considerable strength, for it not only accounts for an overall drop in response time across trials, but it also predicts that the drop will be faster for stimuli to which S has been exposed in pre-experimental trials.

Satiation and Deprivation

✓ Satiation is another process whereby the effectiveness of a stimulus may be reduced, but in this case it is the role of the stimulus as a reinforcing agent, rather than as a conditioned stimulus, that is of special interest. A number of studies have demonstrated that the utility of a stimulus in reinforcing an instrumental response may be decreased by satiation and enhanced by deprivation operations. Two studies by Gewirtz and Baer (1958a, 1958b) illustrate this process with social reinforcers. The experimental task involved dropping marbles into two holes of a container

After establishing a baseline of response, social reinforcement (praise) was given on a fixed-ratio schedule every fifth time S dropped a marble into the hole that had been preferred least during the last minute of the baseline period. Before introducing the experimental task, the preschool Ss were subjected to 20 minutes of social isolation by being left alone in an empty room, to 20 minutes of periodic praise as they performed a simple task, or, in the control condition, received no preliminary experience. The increase in the number of responses to the nonpreferred hole between baseline and experimental periods was greatest following isolation and least following satiation, indicating that the operations had been successful in altering the effectiveness of supportive statements as social reinforcers.

Similar effects have been reported for visual and auditory stimuli. Stevenson and Odom (1961) found that rate of lever-pressing for visual reinforcement increased rapidly following visual deprivation but showed little change after visual satiation. The two conditions were established by leaving 5- to 7-year-old Ss alone in an experimental room for 15 minutes. In the deprivation condition the room was empty and dimly lit and in the satiation condition the room was full of many interesting, colorful toys with which Ss could play.

Odom (1964) controlled Ss' stimulus input more adequately by fitting 8- to 10-year-olds with a space helmet equipped with earphones and a visual tunnel attached to the vision of the helmet. For a 10-minute period the Ss either viewed a uniformly dull visual field or saw a sequence of colors and heard either nothing or a series of varying tones. The experimental task involved turning a small wheel in one direction for presentation of colors and the other for presentation of tones. The number of responses made during 7 experimental minutes differed markedly, depending upon Ss' earlier experiences. The Ss who had been satiated for visual stimuli (and deprived of auditory stimuli) showed an increase in the number of responses that produced auditory stimuli, and the Ss who had been satiated for auditory stimuli (and deprived of visual stimuli) showed an increase in the number of responses that produced visual stimuli. The Ss who had been satiated or deprived of both types of stimuli showed equivalent frequencies of response in each direction.

Although the effects are not as simple as may appear in these sets of studies, there is little question that deprivation and satiation operations alter the effectiveness of relevant stimuli as reinforcers. The use of social reinforcement has proved to be especially complicated, for such factors as sex of S, sex of the experimenter, age of S, and characteristics of the experimenter have been found to be important variables in determining the effectiveness of supportive statements in modifying rate and type of instrumental response (see Stevenson, 1965).

Stimulus Generalization

Stimulus generalization occurs when novel stimuli, similar to the training stimulus and presented for the first time on test trials, elicit the conditioned response. Some degree of stimulus generalization has utility for the organism, but if generalization is too extensive, responses will be made to stimuli that are so dissimilar from the originally effective stimulus that the responses may turn out to be inappropriate. From a developmental point of view, it might be expected that mature Ss will show more restricted gradients of stimulus generalization than will younger Ss. Several studies have found that this is the case. Mednick and Lehtinen (1957) investigated age differences by training Ss to lift their finger from a button when a central light appeared. At the completion of the training trials peripheral lights, arranged on an arc in front of S, were intermixed with reappearances of the central light. The stimulus generalization gradient, as assessed by frequency of response to the peripheral lights, was flatter with 7- to 9-year-old Ss than with 10- to 12-year-olds. Tempone (1965) found a similar effect when MA rather than CA was varied. The Ss were all 8-year-olds, but had mean MAs of 6.6, 8.8, and 10.9 years. Decreasing amounts of stimulus generalization were found with increasing MA.

Why younger Ss show broader generalization gradients is not clear, but one possible basis is suggested in a study by Jeffrey and Skager (1962), who assumed that the greater generalization by the younger Ss may reflect a lack of interest in the task. In the previous two studies, the only reinforcement for correct response during training was verbal encouragement, an incentive that may be less

effective with younger than with older Ss. Therefore, to heighten motivation a training condition was introduced in which Ss received a poker chip for correct response, lost a chip for incorrect response, and were told they later could cash in the chips to see a movie. The procedure was identical for control Ss, except that chips were not given and were not required for the movie. The proportion of 6- to 7-year-olds showing generalization to peripheral lights was significantly smaller with the added incentive than without it, but performance did not differ between the two conditions for 9- to 12-year-olds. Importantly, the performance of the younger Ss in the experimental group did not differ significantly from that of the older Ss. Developmental changes in stimulus generalization may therefore be minimized when younger Ss are highly motivated to respond correctly.)

(Numerous variables have been found to influence stimulus generalization in a series of studies with preschool Ss by Spiker and his colleagues.) All of the studies used lever-pressing as the response and lights varying in hue or brightness as the stimuli. If the strength of the generalized tendency to respond to other stimuli is dependent upon the strength of the conditioned response, increasing the number of training trials should result in a greater degree of stimulus generalization. A study by Spiker (1956a) supported this hypothesis, for the amount of generalization was greater following 24 than following 12 training trials. The effect was replicated in a study of the effect of stimulus intensity on stimulus generalization (Spiker, 1956b). The Ss again were given 12 to 24 training trials, but half were trained with a dim light (2.5 foot-candles) and half with a bright light (250 foot-candles). This study tested the hypothesis that stimulus intensity influences motivational level of S. More intense stimuli are assumed to increase motivation, which, in a multiplicative relation with strength of response, increases the strength of the generalized habit. (The results were supportive of the hypothesis, for a steeper gradient of stimulus generalization was obtained for Ss who had been trained with the bright light.)

In a relevant study, Tempone (1966) varied the number of training trials with Ss at two levels of CA. In line with Spiker's reasoning, it was assumed that generalization

would be increased for younger Ss as the number of training trials increased. With older Ss, however, the opposite effect was predicted. These Ss presumably respond on the basis of some form of mediation. As training increases, the cues defining the effective stimulus should become increasingly redundant, thus increasing the likelihood that a specific, relevant mediating response would be developed which would restrict the degree of stimulus generalization. Two groups of Ss, 6½ to 7½ and 10½ to 12 years old, were presented 15, 30, or 45 training trials in the spatial generalization task. The mean number of responses to the generalization lights decreased for older Ss and increased for the younger Ss with increasing amounts of training, thus supporting the predicted interaction between age and number of training trials.

The effects of providing a verbal mediator on stimulus generalization by preschool Ss was studied by Shepard (1956). After original training and a test for stimulus generalization, the Ss were provided with a common verbal response for the training stimulus and each of the test stimuli. With this type of training, the amount of generalization increased on the second test. Interestingly, however, the increase occurred for only half of the Ss, the other half showed no greater generalization after they had learned a common mediating response than they had in the first test. Even for the former Ss, the mediator was ineffective in raising the level of response for the test stimuli to that found for the training stimulus.

Generalization also may be increased if Ss are trained on multiple rather than single stimuli. White and Spiker (1960), assuming that training with variable stimuli would encourage Ss to generalize, trained an experimental group with three stimuli differing in hue and brightness and a control group with only one of the stimuli. Significantly more generalized responses were made by the experimental group, and younger Ss (42 to 54 months) showed more generalization than did older Ss (52 to 61 months). A final study (White, 1958) investigated the hypothesis that a novel stimulus differing from the training stimulus on only one dimension will elicit more generalized responses than will a novel stimulus differing on two dimensions. The test stimuli differed from the training stimuli in brightness, hue, or brightness and hue. As

predicted, the test stimuli with the more variable attributes elicited fewer generalized responses than did the stimuli differing on only one dimension

These studies leave the status of developmental changes in stimulus generalization unclear. They set forth the possibility that the broader generalization gradients found with younger and duller Ss may be due to motivational processes, but the validity of this argument cannot be assessed until more data are available. Studies with young children indicate that generalization may be increased by using intense training stimuli, extending the number of training trials, using multiple stimuli for training, and by providing a common verbal label for the training and test stimuli. The study by Tempone (1966) is a good example, however, of the desirability of testing children at different ages before concluding that a variable will influence generalization in a specific manner, for depending on the age of S, the variable may produce quite different results.

Extinction

There is only a small number of studies with children on the extinction of instrumental responses, in spite of the importance of this topic in behavior theory. Generally, the experimental variables have been selected from among those used in studies with lower animals. For example, greater resistance to extinction has been found with partial than with continuous reinforcement (e.g., Bijou, 1957, Lewis, 1952, Myers, 1960), with increasing amounts of training (Siegel and Foshee, 1953), and with greater numbers of incentives (Pumroy and Pumroy, 1961). The results are not in uniform agreement, however, for neither a partial reinforcement effect nor an incentive effect was found by Bruning (1964) when speed of response rather than number of responses was used to measure extinction, and Pumroy and Pumroy (1961) reported faster extinction with partial than with continuous reinforcement. The results of several large parametric studies may serve to resolve some of these discrepancies.

Kass (1962) used six percentages of reinforcement (0, 16%, 33%, 60, 80, and 100%) and Ss at four age levels (4, 6, 8, and 10 years) in a study with a simulated slot machine. The Ss were shown how to use the

machine, given 30 trials in which they could win pennies to purchase a prize, and then placed on extinction. The extinction trials continued until the Ss wanted to stop or until they had made 370 responses. Four-year-olds made a significantly smaller number of responses during the extinction trials than the three older groups, and, for all groups, the number of responses decreased significantly as the percentage of reinforcement received during training increased. Nearly as many responses were made by the 0% reinforcement group as by the group that had received 16% reinforcement, thus the inverted U-shaped function between number of responses and percentage of reinforcement reported by Lewis (1952) was not found. The percentage of reinforcement received during training had equivalent effects at the four age levels.

A second study (Kass and Wilson, 1966) used the same general procedure, but the central variable was the number of training trials. Six- and 7-year-old Ss were given 3, 9, 21, 45, or 60 training trials with 33% or 100% reinforcement. Responses made during extinction decreased significantly as the number of training trials increased and were uniformly higher following partial than following continuous reinforcement. An indication of the degree to which children persisted in this task is seen in the fact that after only three trials with partial reinforcement, an average of nearly 240 responses were made during extinction. The results were interpreted as providing support for a discrimination hypothesis of extinction, which states that extinction will be facilitated by the introduction of variables that increase the distinction between acquisition and extinction periods. Accordingly, it should be more difficult for Ss to discern that there has been a change in the schedule of reinforcement with partial than with continuous reinforcement and when only a restricted number of training trials has been presented.

Secondary Reinforcement

A closely related topic—its effects typically are assessed during extinction trials—is secondary reinforcement. Secondary reinforcement is assumed to occur when a stimulus, through its association with a reinforcer, acquires the capacity to influence behavior in a manner similar to that of the original reinforcer. The concept is used to explain the ap-

parent strengthening of responses by what seem to be neutral stimuli, but a review of the experimental findings leaves the impression that it is an elusive process that is not readily demonstrated with human Ss. In fact, Longstreth (1966, p. 26), after reviewing the literature, concluded that "it becomes reasonable to argue that the phenomenon has not yet been clearly demonstrated with human Ss" and cites methodological and interpretive problems in many of the studies that seem to have yielded evidence for its occurrence. Longstreth's main criticisms are (1) there is a lack of evidence that groups receiving primary reinforcement behaved differently from those that did not, thus calling into question the basis for the conditioning of secondary reinforcers, and (2) the task may be constructed so that the sequence of responses leading to primary reinforcement serves to elicit the response on the subsequent trial rather than strengthen the preceding response. In view of the confused status of the concept, perhaps the most expeditious approach to reviewing the studies is to indicate the studies in which the effect has and has not been found.

A study by Sidowski, Kass, and Wilson (1965) illustrates some of the complexities. Their goals were to separate the potential cue and reinforcing functions of the neutral stimulus. The stimulus, a light, appeared (1) before and during response, (2) with the delivery of the primary reinforcer, a penny, or (3) during both the time of response and the delivery of the penny. The greatest number of responses occurred during extinction when the light was directly associated with primary reinforcement and the fewest, when the light served as a cue for response. The presentation of the light during both response and delivery of reinforcement resulted in an intermediate number of responses. The overall analysis of the data did not reveal a significant difference in the number of responses made when the light was present and when it was absent during the extinction trials, although a median split on number of responses indicated a greater number of Ss above the median when the light was present during the extinction trials.

The Myers (Myers and Myers, 1965) have published a large number of studies on secondary reinforcement and have been particularly interested in testing a discrimination

hypothesis of secondary reinforcement. This hypothesis predicts that the strength of a response when primary reinforcement is absent is a function of the degree of similarity between the patterns of stimulation occurring in conditioning and in the test trials. From their studies, many of which are extremely elaborate, they have concluded that "the discrimination hypothesis accounts for data resulting from a choice between two responses, only one of which produces a secondary reinforcer. Under other test conditions, the method of conditioning is not relevant and secondary reinforcement is strongest when its percentage of occurrence is greatest" (p. 101). These studies received the brunt of Longstreth's (1966) criticisms.

The elusive nature of the secondary reinforcement effect is evident in a study by Kass, Beardshall, and Wilson (1966) where the apparatus and general procedure of the Sidowski, Kass, and Wilson (1965) study were used. A secondary reinforcement effect was not obtained. Seven- and eight-year-olds were tested with the simulated slot machine and either half or all of their responses were reinforced with a penny for 24 trials. A light was paired with the delivery of the penny for half of the Ss in each condition, and for the other half the light was absent. During the extinction trials a light appeared for half of the Ss and for the other half it did not. Only the percentage of reinforcement received during training exerted a significant effect on the number of responses made during extinction; the number was higher following 50% than following 100% reinforcement. Kass and Wilson (1966) reported a second nonconfirmatory study. Although number of training trials and percentage of reinforcement, the major variables investigated, significantly influenced performance, there was no indication that pairing a light with the delivery of the primary reinforcer had any significant effect on performance.

Longstreth (1966) has argued that what may appear at times to be a secondary reinforcement effect is actually the result of frustration that occurs when a cue is no longer followed by reinforcement, and he has presented several studies to support such an interpretation. For example, children were tested in a situation in which either a bright or a dim light led to reward and the other

did not. Three stimulus conditions were operative during extinction: (1) the positive cue and the sound that accompanied the delivery of the reward, (2) the positive cue alone, and (3) the negative cue alone. Resistance to extinction was fastest in the first condition, a result opposite from that predicted from a secondary reinforcement hypothesis, but in line with predictions from a frustration position.

The final group of studies related to secondary reinforcement includes those of Nunnally and his associates, who have isolated some of the behavioral consequences of pairing a neutral stimulus with primary reinforcement. The apparatus used in most of these studies was a spin-wheel in which a pointer stopped on one of two or three nonsense syllables. When the pointer stopped on one, a penny was delivered; when it stopped on the others, the Ss had to give back a penny or nothing happened. In two studies (Nunnally, Duchnowski, and Parker, 1965; Nunnally, Stevens, and Hall, 1965) the nonsense syllable leading to reward later was described in more favorable terms than were the other nonsense syllables; it was more often expected to be associated with reward in another game, and it was looked at longer in a "looking box" than were the other nonsense syllables.

A study by Parker and Nunnally (1966) replicated these effects and found, in addition, that varying the percentage of reward in training affected the Ss' expectancies of receiving a reward from an object bearing the name of the nonsense syllable but did not influence other measures of response significantly. A final study (Nunnally, Knott, and Duchnowski, 1967) varied the amount of practice on the original task (5, 15, or 30 trials) and compared the effects of actually obtaining or relinquishing rewards versus defining the reward conditions as those that would prevail when the Ss played the game at a later time. Neither variable had a significant effect on performance. In this study, however, the nonsense syllable that led to reward or that was defined as the one that would lead to reward was evaluated more favorably and was more frequently expected to lead to reward in another game than were the other nonsense syllables, but perceptual responses, such as time spent viewing the syllable, eye movements, and pupillary re-

sponses, were not significantly different for the three types of nonsense syllable.

Research on secondary reinforcement is more disjointed than is the research in many other areas. The most dismaying aspect of the studies is that, with the same apparatus and procedure, the results are sometimes positive and more often negative. Because of the critical importance of the temporal relations among the various events involved in a study of secondary reinforcement, great care and control will be necessary before satisfactory statements about the utility of the concept can be made.

Behavior Modification

The discussion thus far has consisted of a review of laboratory studies, but the techniques of instrumental or operant conditioning also have been applied successfully to the treatment of a wide variety of behavior problems in children. The success appears to be attributable not only to the systematic control of the outcomes of behavior, but also to astute analyses of the effective conditions of reinforcement and to the confidence necessary to attack some of the most intractable types of behavior.

A study by Baei (1962) illustrates how a common form of undesired behavior, thumb-sucking, is influenced by the systematic withdrawal of positive reinforcement. Two Ss with a high incidence of thumb-sucking were shown animated cartoons. Whenever one of the Ss sucked his thumb the projector was turned off; the film continued only when S removed his thumb from his mouth. Thumb-sucking decreased in this S, but not in the second S, run in a yoked fashion with the first S but for whom the withdrawal and presentation of reinforcement were not contingent upon the thumb-sucking response. Lovaas, Freitag, Gold, and Kassorla (1965) have shown that withdrawal of reinforcement may also be effective in modifying a much more severe form of behavior, self-mutilation. Adults typically are astonished by such behavior and attempt to intercede by responding to the child when he commits such acts. The Lovaas et al. study clearly indicates the frequency of self-mutilation can be effectively decreased if the adult ignores rather than responds to such acts.

Noxious stimuli have also been used with

success Lovaas, Schaeffer, and Simmons (1965) associated the presence of an adult with the cessation of electric shock. Autistic children, who previously had displayed minimal awareness of adults, learned to approach and embrace adults through this procedure. Shock has been used as a last resort and only with the most severely disturbed children, reliance usually is placed on application of positive forms of reinforcement. In a typical study, Patterson, Jones, Whittier, and Wright (1965) attempted to increase a hyperactive child's attention to what was going on in school. The child was equipped with a small earphone and a buzz in the earphone was established as a secondary reinforcer by being paired with candy during preliminary training. The child and the class were told that if the child sat still all would receive candy. A decrease in the frequency of the child's non-attentive responses was noted when a buzz was presented following each 10-second interval in which the child was attentive.

Many other studies of behavior modification with children could be discussed, such as those directed at increasing sociability (Allen, Hart, Buell, Harris, and Wolf, 1964), reducing aggression (Brown and Elliott, 1965), treating enuresis (Ellis, 1963), eliminating phobias (Lazarus, 1960), teaching autistic children to speak (Lovaas, Berberich, Perloff, and Schaeffer, 1966), and improving reading skills (Staats and Butterfield, 1965). Such a discussion would serve primarily to illustrate how extensively the techniques have been applied. The effects of the studies of behavior modification on child psychology have been healthful, for they offer vivid, and sometimes dramatic examples of how principles derived from laboratory experimentation may be applied successfully to the solution of practical problems.

DISCRIMINATION LEARNING

In contrast to studies of conditioning, where the approach is often highly empirical, interest in the study of children's discrimination learning began when child psychologists attempted to find out how well Spence's (1936, 1956) treatment of discrimination learning could predict the performance of children. It did not take long to see that the child was too complex for the model that had

been developed to account for the behavior of nonverbal organisms. This is not surprising, for the manifest simplicity of a discrimination learning task conceals a bewildering array of psychological processes. In a typical study, all that is asked of the child is that he select the correct stimulus from an array of two or more stimuli. Each time he chooses the stimulus deemed to be correct by the experimenter he discovers some prize or other indication that he has been correct. Eventually, if the problem is of an appropriate level of difficulty, he begins to choose the correct stimulus consistently. However, in presenting the problem to the child, a number of implicit assumptions are made. It is assumed that he is capable of attending to the relevant stimuli, of inhibiting attention to irrelevant cues, of discriminating the differences among the stimuli, of remembering the stimulus chosen, of being appropriately influenced by the consequence of his response, of being motivated to persist in trying to be correct, and of not elaborating the problem so that it becomes more difficult than it actually is. Thus what is often assumed to be one of the simplest forms of learning turns out to have many complex aspects.

Characteristics of the Stimuli

It is obvious that gross differences among stimuli will influence the rate of discrimination learning. But subtle differences among stimuli and their physical and temporal relation to response and reward also have been found to have significant effects. Since most of the studies have used visual materials, the discussion will center on visual stimuli.

The dimensionality of stimuli may vary, that is they may be two-dimensional patterns, planometric (depth is minimized), or stereometric (all three dimensions are fully represented). The influence of this attribute is clearly demonstrated in three studies, all with 3-year-old Ss, which found large differences in the average number of trials required by the children to learn a two-choice size discrimination: 335.8 (Kuenne, 1946), 54.8 (Alberts and Ehrenfreund, 1951), and 13.6 (Stevenson and Langford, 1957). Although the experimental procedures differed in several ways, a critical difference appears to be the way in which the stimuli were presented. In the first study the stimuli were patterns

mounted on the doors of the boxes containing the incentives, in the second the incentive boxes were equipped with square doors of different sizes, and in the third the stimuli were blocks which S lifted to reveal the incentive. The use of blocks or doors as stimuli may have aided in divorcing the stimuli from a common background and in increasing the number of cues available to the Ss by requiring them to manipulate the stimuli. Stevenson and McBee's (1958) later finding that a three-choice size-discrimination was learned more readily when the stimuli were stereometric than when they were planometric or patterns affirms the importance of stimulus dimensionality on learning, as does the finding of Dornbush and Winnick (1966) that a square and rectangle are discriminated more easily when they are represented by stereometric as contrasted to planometric objects. The only contradictory evidence is found in a study by Kerpelman (1967) in which children learned to discriminate among irregular pentagons more rapidly when they were planometric than when they were stereometric. In such a complex discrimination the addition of a third dimension may have provided additional cues that confused rather than aided the Ss.

Spatial relations between stimulus, response, and reward may exert a significant effect on rate of learning. Murphy and Miller (1959) found that fewer trials were required by 10-year-olds to learn a two-choice discrimination if the cue and the locus of response and reward were contiguous than if they were separated. Similar findings were obtained in a more elaborate study with preschool Ss by Jeffrey and Cohen (1964). Learning was most rapid in a condition where the stimulus, response, and reinforcement were contiguous (S lifted a block to find the reward), and little change in performance occurred when all three components were separated spatially, or when there was contiguity of stimulus and reward or response and reward with separation of the other component. Since a high level of learning occurred in a group for which the stimulus and response were contiguous but the locus of reward was separated, it was concluded that the most important combination was the contiguity of stimulus and response. The results support the notion that Ss often restrict their

attention to the locus of response, thus if the stimulus is near this area, differences among the stimuli are more likely to be observed.

Another important influence on rate of learning is the procedure by which the stimuli are presented. Two common procedures have been used in studies of discrimination learning: the simultaneous discrimination, as previously discussed, and the successive discrimination. Two or more different stimuli are presented on each trial in the simultaneous problem, whereas in the successive problem only one of the stimuli is presented on each trial. In the first, S's task is to learn to choose the stimulus that leads to reinforcement (e.g., the black stimulus), in the second, S must learn to make different responses to the various stimuli (e.g., choose "right" when the stimuli are black, "left" when they are white). The simultaneous problem has been found to be easier for children in a number of studies (Erickson and Lipsitt, 1960; Horowitz and Armentrout, 1965; Jeffrey, 1961; Rieber, 1964; Spiker and Lubker, 1965), but this is not always the case. Although the simultaneous problem may be easier than the successive problem when response is made directly to the stimuli, the opposite effect has been found when the stimulus and response are spatially separated (Lipsitt, 1961).

It appears that any procedure which increases the likelihood that Ss will compare and contrast the stimuli and thereby isolate their distinctive and relevant characteristics will result in faster learning. Evidence to support such a conclusion has been reported by Rieber (1966b), who forced Ss to delay their response following the simultaneous or successive presentation of stimuli (colored lights). When there was stimulus feedback, that is, when the stimulus reappeared as S responded to it or when all stimuli reappeared as S responded, the simultaneous problem was easier than the successive problem. When there was no feedback, the successive problem was easier. It was assumed that the reappearance of the stimuli emphasized their relevant characteristics, but without feedback the importance of the relevant dimension—color—was obscured by the simultaneous presentation of stimuli whose position also differed on different trials.

A direct test of the possibility that the presence of irrelevant dimensions may retard learning has been reported by Lubker (1967). Three groups of 8- to 10-year-olds were presented a two-choice simultaneous discrimination problem in which the relevant dimension was form. Blocks varying in form, brightness, and size were used for all groups of Ss, and the blocks were combined in different fashions to constitute three series of pairs of blocks which differed in the number of irrelevant dimensions presented. For one group, each pair of stimuli differed only in form; in a second, they also differed in brightness; and in a third, they differed in form, brightness, and size. Significantly slower learning occurred when either one or two irrelevant dimensions were present. The same result was found in a very similar study by Osler and Kofsky (1965) with 4-, 6-, and 8-year-olds in a discrimination task involving stimuli that varied in form, size, and color. Developmental changes were found in the children's tendencies to respond to the irrelevant cues. When the sequences of Ss' responses were analyzed, it was found that the two youngest groups responded more frequently to the irrelevant dimensions and to position cues than did the 8-year-olds.

The degree to which learning is retarded by the presence of irrelevant information is one index of how information may be used by children in guiding their response. Another index is the degree to which learning is *facilitated* when the superfluous information is redundant rather than irrelevant. Emas (1965) gave kindergarten children a series of two-trial problems in which the cues varied in a systematic manner between the first and second trials. Performance improved in an orderly manner on trial 2 as the number of redundant cues increased. Even though the second problem could be responded to correctly on the basis of differences in one of the components, learning was more efficient when compound cues were available.

The remarkable degree to which children scan stimuli in their efforts to solve problems is seen in a study by White (1965) in which the cues were ever-changing. For example, if on a particular trial one of the two stimuli included a small square superimposed on a large square, only the small square along with

two vertical lines functioned as this stimulus on the subsequent trial. When the child responded correctly on this trial, the stimulus was transformed into one vertical line with a second line attached to a circle on the next trial, and so on through multiple changes, with each new stimulus retaining only a portion of the attributes of its immediate predecessor. Ten- and eleven-year-olds were capable of tracking such variations when they occurred for the positive stimulus, and although the Ss seemingly paid little attention to such changes in the negative stimulus, three-fourths of the Ss subsequently were capable of learning a problem in which changes were made in both the positive and negative stimuli. A less complex, related design was used by Walk and Saltz (1965), in which the number of positive and negative cues differed. Eight- and 9-year-olds performed better when there was a single positive than when there was a single negative cue, again indicating a greater tendency for children to be influenced by variations in the positive cue.

From this discussion we might deduce that children utilize all aspects of the stimulus situation with equal effectiveness in learning a discrimination problem. That they do not is illustrated in a series of studies in which the relevant cue coincides with or is discordant with the child's preferences. For example, after the fourth year children generally prefer form over color, even though below that age they tend to prefer color over form as a means of classifying stimuli (Suchman and Trabasso, 1966a). Suchman and Trabasso (1966b) have demonstrated with 10-year-olds that children who, in pretesting, showed a preference for form over color later learned to sort cards faster by form than by color, with the opposite effect occurring for children who preferred color over form. Smiley and Wen (1966) and Mumbaer and Odom (1967) have demonstrated similar effects in studies of color and form discrimination with kindergarten and preschool Ss. In a related experiment, Wolff (1966) found that some 7-year-old children preferred height and some preferred brightness as a means of classifying stimuli. When the children later were presented a two-choice discrimination utilizing stimuli that differed both in height and brightness, those who had preferred

brightness learned a brightness discrimination more rapidly than a form discrimination and those who had preferred form learned the form discrimination more rapidly. Shepp (1963) found another example of how the choice of stimuli may affect learning in a study where pieces of candy were used both as discriminative stimuli and as reinforcers. More rapid learning occurred when the reward was candy of the same form and color as the positive cue than when it was dissimilar to both the positive and negative cues, or when it was identical to the negative cue. Thus the tendency to select a stimulus was greater when it was identical to the one functioning as the reinforcer.

These studies of stimulus factors indicate that children's performance cannot be subsumed under a theory such as Spence's, which conceptualizes discrimination learning as the result of incremental changes in the strength of approach and avoidance tendencies occurring as a consequence of reinforcement and nonreinforcement. Stimuli appear to function as sources of information for children, rather than as cues that elicit differential tendencies to respond. Seemingly small changes in the stimuli and the manner in which they are presented may produce striking differences in the rate of learning, and, on the other hand, radical changes in the stimuli do not necessarily mean that the child will fail to find relevant characteristics in the stimuli that provide a basis for correct response. Furthermore, the results of studies in which data from individual children are considered or in which the course of learning is plotted "backwards" from the point at which criterion is met indicate that discrimination learning may not be a gradual process. In either of these cases, evidence has been found for an initial plateau in which little improvement in performance takes place, followed by a period of rapid acceleration in the frequency of correct response (Rieber, 1966a, White and Plum, 1964, Zeaman and House, 1963). Such curves have been interpreted as indicating that two stages are involved in discrimination learning: an early phase in which *S* learns to attend to and discriminate among the stimuli, and a second, rapid phase in which the correct response is attached to the positive stimulus.

An important question that is not con-

sidered by such two-stage models is how *S* discriminates among the stimuli. Is it a result of learning the distinctive features of the objects that are to be discriminated, or is it a result of matching sensory data to schema of objects that have been built up and refined through experience?

Pick (1965), studying reactions of *Ss* to six letterlike forms and their transformations, found that the detection of distinctive features may be the necessary and sufficient condition for improvement in discrimination when simultaneous comparison of objects is required. Pick, Pick, and Thomas (1966), employing essentially the same design and similar stimuli in a study of cross-modal transfer, obtained results supporting Pick's earlier observations. These studies are discussed in detail in Chapter 13 of this book.

What appears to emerge is a three- rather than two-process model of discrimination learning: the child must learn to attend to the stimuli, isolate the distinctive features that differentiate the stimuli, and attach the appropriate response to the stimulus leading to reward. The studies reviewed have been concerned primarily with the first two processes and indicate that the characteristics of the stimuli may facilitate such learning when the situation involves few irrelevant cues, the cues are redundant, the stimuli are presented near the locus of response, the mode of presentation provides an opportunity for contrasting the stimuli, and when the reinforced cue is in accord with the child's preferences.

Stimulus Pretraining

Other explorations of the influence of stimulus factors on discrimination learning have been concerned with the degree to which stimulus pretraining influences subsequent discrimination learning. These studies have been directed at assessing the utility of various theoretical analyses of discrimination learning. The two interpretations of the effects of stimulus pretraining on later learning that have received the greatest attention are those dealing with the development of observing responses and with the acquired distinctiveness of cues. The first postulates that learning may be facilitated if *S* learns to make observing responses "which, when made to one or the other of a given pair of

stimulus complexes which are different, consistently results in distinctive stimulation from those two complexes" (Kurtz, 1955, p. 290). According to this view, pretraining may aid later learning by directing S's attention to the properties or dimensions of the stimuli that subsequently provide the cue for differential response.

The hypothesis of acquired distinctiveness of cues has been offered as a mechanism for accounting for the more rapid learning that occurs when Ss, in pretraining, have attached distinctive verbal or motor responses to the discriminative stimuli. It is assumed that the distinctive responses reduce stimulus generalization by making the total stimulus complex associated with each cue more distinctive. The stimulus complex is viewed as consisting of the external stimulus and the stimuli produced by the distinctive verbal or motor responses. A complementary hypothesis dealing with the acquired equivalence of cues is applied when a common verbal or motor response is attached to the discriminative stimuli during pretraining. In this case, stimulus generalization is assumed to be increased and the efficiency of learning impaired by the presence of an element common to all of the discriminative stimuli.

A third hypothesis was proposed by Spiker (1956), who suggested that verbal responses attached to the discriminative stimuli during pretraining may facilitate later learning by making it easier for the S to rehearse the correct associations during the intertrial intervals. Although various forms of preliminary experience with the discriminative stimuli have been found to aid later learning, it has not been possible to design studies that offer exclusive support for a particular hypothesis. (For a detailed review of these studies, see Cantor, 1965.)

A typical experiment is that of Norcross and Spiker (1957) in which preschool children were pretrained with pictures of faces. One group learned distinctive names for pictures of two female faces, a second group learned distinctive names for pictures of two male faces, and the third had to respond to the female faces by saying "same" or "different," depending upon whether or not the faces were identical. Following pretraining the Ss were presented a two-choice discrimination task in which the female faces

were the discriminative stimuli. The first group performed significantly better on the discrimination task than the second or third groups, but the latter groups did not differ significantly in incidence of correct response. The possession of verbal labels thus enhanced performance on the discrimination task, but learning to orient to the distinctive features of the discriminative stimuli did not result in more efficient performance than did pretraining with a different set of stimuli.

Several of the difficulties that arise in research on stimulus pretraining are evident in this study. The Ss had more difficulty in learning to associate names with the female faces than in determining whether or not the pair was identical, thus the amount of pretraining experience with the stimuli differed for the first and third group. Second, it is questionable whether learning names for the pair of male faces constituted irrelevant pretraining, for the discovery of the bases of the differences between these faces involved comparison of the same facial features as was required later in the discrimination learning task. It is therefore impossible to determine whether or not a particular theoretical position was supported by the results of this study. In addition, the lack of a control group receiving no pretraining makes it impossible to ascertain whether the results reflected facilitation in the performance of the first group or interference in the performance of the last two groups.

Two additional problems encountered in studies of stimulus pretraining were avoided in a design used by Norcross (1958) to study the effects of similarity of previously acquired stimulus names on discrimination learning. A within-Ss design controlled for nonspecific transfer resulting from the effects of warm-up and learning-to-learn. If some Ss are required to learn names of the stimuli during pretraining and others are not, later differences in discrimination learning may be a result of the Ss' prior learning experience in the experimental setting. In Norcross' study, each S learned distinctive names to one pair of stimuli and similar names to a second pair during pretraining. As would be predicted from the hypothesis of acquired distinctiveness of cues, a higher level of performance was found for the pair of stimuli with distinctive names in the subsequent discrimination

learning task involving both pairs of stimuli

Reese (1960) extended Noircross' study to include different amounts of pretraining. In a carefully counterbalanced design, Ss were given no pretraining on one pair of stimuli, moderate pretraining on a second, and extended pretraining on a third. Although level of pretraining had no generally significant effects on discrimination learning, the pair of stimuli with distinctive names elicited better performance than did the pair not presented during the pretraining trials. For names of intermediate similarity, a high level of pretraining produced better performance than no pretraining. No facilitation was found with either level of pretraining when the names were extremely similar. Thus whether or not distinctive names facilitated learning depended on how well the names had been learned. A second study by Reese (1961a) also revealed no significant differences in ease of learning following different degrees of pretraining. Only in the early phases of test performance did the presence or absence of prior experience with the test stimuli influence the children's choices.

A somewhat different approach to evaluating the effects of stimulus pretraining was taken by White (1961), who assumed that pretraining with varied stimuli, each consistently yielding reward, would induce Ss to minimize or overlook stimulus differences in a later discrimination learning task. Preschool children were given 24 trials with (1) one of the discriminative stimuli, (2) a stimulus that was not used in the discrimination task, or (3) three different stimuli, one of which was included in the discrimination task. Other Ss were given eight trials with one of the discriminative stimuli or were given no pretraining. (The discriminative stimulus used in pretraining was always the stimulus that led to reinforcement in the discrimination learning task.) The facilitating effects of warm-up were reflected in the fact that any form of pretraining resulted in more efficient learning than did no pretraining. Earlier experience with varied stimuli led to poorer performance than did experience with the discriminative stimulus, but the number of the pretraining trials was not a significant variable in influencing performance. The conclusion that pretraining with varied stimuli had a detrimental effect on later performance is marred, how-

ever, by the fact that the performance of Ss pretrained with the irrelevant stimulus differed significantly only from that of the Ss given no pretraining.

(A final set of three studies indicates that stimulus pretraining may or may not be helpful, depending upon the consequences of the responses made during the pretraining period. Spiker (1959) presented preschool Ss with a two-part discrimination learning task. One group was given 24 preliminary trials in which a bright light was the positive cue and a dim light was the negative cue, followed by 24 trials in which a medium-bright light was substituted for the dim light. The study was undertaken to test the hypothesis that the use of highly similar stimuli during the preliminary phase would retard the development of appropriate orienting responses. The fact that the first group performed at a higher level during the terminal 24 trials than did the second group supports such a hypothesis, but another plausible explanation of the results is that the difficult task was frustrating and that frustration-produced responses disrupted subsequent performance.)

† Possible frustrating effects of pretraining also were found by Stevenson and Pionnikoff (1958), who gave preschool Ss pretraining trials with all three of the forms that were later used in a discrimination learning task. One group of Ss received 100% reinforcement, that is, all choices made during pretraining were reinforced. Another group received 50% nondifferential reinforcement, and a third group received 0% reinforcement. A fourth group received no pretraining. The results differ from those found by White (1961) where pretraining was given with only one of the discriminative stimuli, for the 100% group and the control group showed equivalent rates of learning. Both groups learned more effectively, however, than did the 50% and 0% groups. The effects of frustration were evident in the performance of the last two groups, thus either inconsistent or no reinforcement during stimulus pretraining may produce effects that interfere with later learning. Such a possibility was supported in a study by Steigman and Stevenson (1960), where the pretraining was given with stimuli different from those used in the discrimination learning task. A low level of

reinforcement during pretraining resulted in significantly poorer performance on a discrimination learning task than did high levels of reinforcement during pretraining.

The conclusions that can be derived from these studies are of relatively low order. It has been extraordinarily difficult to establish control groups that make it possible to interpret the results as providing definitive support for a particular hypothesis. Whatever the mechanism, there seems to be little disagreement that later discrimination learning is facilitated if the *S* learns distinctive names for the stimuli during pretraining and that such variables as the relative distinctiveness of the names and the amount of pretraining significantly affect the degree of facilitation that will occur. Further, any pretraining that increases the likelihood that the *Ss* will discover the distinctive features of the stimuli appears to facilitate later learning. Prior familiarization with the discriminative stimuli is not in itself sufficient to produce facilitation, for the effects of such familiarization depend upon such conditions as the reinforcement provided during pretraining and the other types of stimuli that are presented.

Reinforcement and Incentive Effects

Implicit in the design of any study of discrimination learning is the fact that response to only one member of the set of stimuli will be designated as correct. The experimenter must then decide how the child will be informed of the appropriateness of his response. A review by Bijou and Sturges (1959) of the types of stimulus and event that have been used as positive reinforcers indicates that information about the correctness of response has been imparted in a variety of ways, and in many studies the incentive conditions selected by the experimenter have been found to play a significant role in determining the course of children's performance.

Children in many ways are uncharitable *Ss*, for they often fail to behave in the manner predicted by learning theories or, in some cases, even by common sense. The vagaries of their behavior are strikingly evident in some of the studies of reinforcement effects on discrimination learning. A good example is the study by Miller and Estes (1961) in which 9-year-old boys received either a

signal light, 1 cent, or 50 cents for each correct response in a two-choice discrimination task. The last two groups also had to forfeit the same amounts for each error. Not only did the *Ss* given a monetary reward perform significantly more poorly than the control group, but the group receiving 50 cents for correct response performed no better than the group receiving only 1 cent. How can such a finding be interpreted? First, elementary school children enter most experimental situations with a high level of motivation to perform well. Although they may have some trepidation about the strange situation, and indeed older children often appear to be very anxious about how well they will perform, such concerns usually are dispelled by the benign characteristics of most learning tasks. Thus, in contrast to what occurs when lower animals are used as *Ss*, the experimenter is faced with an eager and expectant *S* whose behavior is not easily controlled by physical sources of reinforcement. It is sometimes the case, and this appears to have occurred in the Miller and Estes study, that physical reinforcement is distracting and results in the *S*'s dividing his attention between the accumulated rewards and the discriminative stimuli.

The Miller and Estes results have been substantiated in other studies, such as one by Terrell, Durkin, and Wiesley (1959), in which middle-class *Ss* learned a two-choice size discrimination more rapidly when a correct response was followed by a light than when it was followed by the light and a piece of candy. However, the performance of lower-class *Ss* included in the study places an important restriction on the results obtained with middle-class *Ss*, for the lower-class *Ss* performed more effectively when they were reinforced with candy than when they merely received a signal for correct response. It was assumed in designing this study that middle- and lower-class children differ in the degree to which they have learned to value nonmaterial incentives, and the significant interaction between social class and incentive effects supports such an assumption.

Subtle differences in incentive conditions may change the outcome of a study. Terrell (1958), for example, found no significant difference in performance among *Ss* whose

correct responses were reinforced by a signal light, a piece of candy, or by allowing Ss to transfer a bean from one jar to another with the expectation that they could trade the beans for a bag of candy when they had enough of them. The signal light also followed correct response for the last two groups. A fourth group of Ss, who simply were promised a bag of candy after they had made the light go on enough times, performed more poorly than any of the other groups. Evidently, the vagueness of a promise with no accompanying evidence of progress or indication of what constituted attainment resulted in a deterioration of performance. Or was it that the children in the "promise" group were prohibited from making meaningful manipulative responses that, in themselves, may constitute a source of reinforcement? This possibility was studied by Terrell (1959), who told the Ss to imagine they received a piece of candy after each correct response and to put the imaginary candy in a make-believe bag that later could be exchanged for a real bag of candy. The Ss who had engaged in manipulation of the imagined objects learned a two-choice discrimination in significantly fewer trials than Ss who simply were promised a bag of candy when they made the light go on enough times.

These results do not mean that children are insensitive to the presence of material incentives in a discrimination learning task, since the studies typically involved a single testing session and arbitrary assignment of the child to a particular incentive group. Conditions can be arranged to reveal significant differences in performance as a function of the incentives used. Brackbill and Jack (1958) made the reasonable assumption that the effectiveness of different objects as incentives or reinforcers may differ, depending upon individual preferences. In their study, kindergarten boys either were allowed to select the incentive they wished to work for from among a group of three, or they arbitrarily were assigned one incentive. As predicted, the variability in the average number of trials required to meet criterion for learning a three-choice discrimination problem was greater for the group whose incentive was assigned.

Another effort to assess differential effects

of incentives is a study with 10-year-olds by Witryol, Tyrrel, and Snowden (1964), who used a five-choice discrimination task. Each of the five stimuli was consistently paired with one of five incentives: a piece of bubble gum, a penny, a toy charm, verbal reinforcement, or nothing. Two indices of possible differences in the effects of the incentives were the rank-order of frequency of choices of each stimulus and changes in the frequency of choices across trials. The stimulus yielding a penny was chosen most frequently and the stimulus yielding nothing was, reasonably, chosen least frequently. The Ss selected the other three stimuli with roughly equal frequency. However, for boys, only choices of the stimulus that yielded a penny increased significantly across trials, and for girls, only the stimulus associated with supportive comments from a young male experimenter.

Two other studies found that a higher level of performance may occur if there is a possibility that the incentive will be retrieved by the experimenter when S makes an incorrect response. Brackbill and O'Hara (1958) gave kindergarten boys 15 pieces of candy and told some of the Ss that each time they made a correct choice they would find another piece of candy, but that each time they made an incorrect choice they would have to return a piece to the experimenter. Another group was not required to return the candy when they made incorrect choices. Learning was significantly faster for the first group, perhaps because the value of an incentive is increased when there is a possibility of losing it. But it is also possible that the introduction of a mild form of punishment results in S's paying closer attention to the discriminative stimuli.

Similar results were found by Stevenson, Weir, and Zigler (1959). In an effort to vary the amount of pre-experimental satiation for the incentive objects, the Ss were given either 5, 10, 20, or 40 colored stickers in the pre-experimental period. The Ss received a sticker for each correct response and half of the Ss were required to return a sticker after each incorrect response. Only those groups given the two smaller numbers of stickers and required to relinquish a sticker following incorrect response tended to learn the three-choice successive discrimination problem.

Over 80% of these Ss reached the criterion for learning, but 30% or fewer of the Ss in the other groups did so. The effects of introducing a penalty for incorrect response were dependent upon the number of incentive objects the Ss had available.

✓ Facilitating effects of mild forms of punishment also have been found in studies where the punishment involved more than the penalty of returning prizes for incorrect responses. Penney and Lupton (1961), in line with the preceding results, found a higher level of performance in a two-choice pattern discrimination when children received candy for correct response and an unpleasant tone for incorrect response than when they received only candy for correct response. In fact, the second group continued to perform at a chance level throughout the task. A third group, which received only the tone for incorrect responses, showed the highest level of performance.

In a related experiment, Spence and Segner (1967) found that children presented candy for correct response and a buzzer for incorrect response learned a series of object discriminations more effectively than did a group receiving only reward for correct response. No significant difference was found between the performance of the group given both candy and the buzzer and a third group given only the buzzer. The study included complementary groups for whom the words "right" and "wrong" constituted the reinforcers. There were no significant differences in performance among the verbal reinforcement groups. Of additional interest is the finding that there was no significant difference in the effectiveness of material and nonmaterial rewards for middle- and lower-class children, a result different from that found by Terrell, Durkin, and Wiesley (1959). Spence and Segner were careful to point out the informational value of the presence or absence of reinforcement for a particular response, thus the Ss' set was presumably quite different in this study from that of the Ss in the other studies discussed. The interpretation favored by the authors for the poor performance of the candy-only group was that the delivery and accumulation of rewards may distract attention from the task and thereby interfere with performance.

Silence as used in studies such as the preceding one may play a different role, depending upon whether it is paired with the experimenter's saying "right" or "wrong." Offenbach (1966) has shown that silence acquires reinforcement value in a direction opposite to the verbal statement with which it is combined. That is, silence may acquire a positive value when the word "wrong" follows incorrect responses and a negative value when "right" follows correct responses. Silence therefore may impart different information, depending upon the S's expectations or prior experience.

† Finally we consider what would happen if an intense form of punishment were used. Strong electric shock has been found to have strong effects on learning in lower animals. Nelson, Reid, and Taveis (1965) attempted to determine whether such a strong aversive stimulus would result in similar effects with children. In a study that probably will not be repeated because of its ethical problems, children received either a tone, the words "right" or "wrong," or strong electric shock as feedback for correct and incorrect responses in tasks where one of two responses had to be associated with a series of words, or of combinations of letters or numbers. Despite the fact that the shock was so strong that it produced tears in some children, no significant differences in rate of learning were found among the various conditions. In contrast to animals, children appeared to respond to the informational value of the shock, rather than to its aversive qualities, in directing their response.

These studies, and others to be discussed in later sections, indicate the inappropriateness of mechanistic interpretations of the role of reinforcers and incentives in children's discrimination learning. Reward does not necessarily facilitate the acquisition of the correct response, nor does punishment necessarily decrease the tendency to make incorrect responses. Because children are social organisms who are highly dependent upon the manner in which the adult structures the task and who enter the experimental situation with preferences and great varieties of prior experiences, their interpretation of what is defined as a reward or a punishment and the way their performance is influenced by them may be very complex. As Spence and Segner (1967, p. 37) have pointed out, "it is be-

coming increasingly apparent that reinforcers do not have a simple set of properties that affect performance in a uniform manner but may play a number of complex roles, depending on such variables as the characteristics of the subjects, the task, the nature of the reinforcers themselves, and the precise manner in which they are introduced into the situation."

Delay of Reinforcement

There is a great deal of evidence that a delay in the time of reinforcement retards animal learning, but the findings with children are inconsistent. The majority of the studies of children's discrimination learning have found negligible effects of delaying reinforcement, but differences in the performance of groups receiving immediate and delayed reinforcement have been found in some studies. Several examples reveal the disparities among these sets of results. In a study by Ross, Hetherington, and Wray (1965) delays as long as 18 seconds did not significantly influence performance when the stimuli were not visible during the delay period, when the stimuli were visible, learning was retarded by a 12- but not by an 18-second delay. Hetherington, Ross, and Pick (1964) found significantly slower learning when the delay was 12 seconds, but not when it was 1.5 or 6 seconds. No effects of delays of 3 or 6 seconds were found by Erickson and Lipsitt (1960) in a three-choice discrimination problem. In a summary of seven studies by Blackbill and her associates involving 14 comparisons, immediate reinforcement resulted in faster acquisition in only one case (Blackbill, Wagner, and Wilson, 1964). On the other hand, two studies of form and size discrimination have found significantly slower learning for groups receiving a 7-second delay than for those receiving immediate reinforcement (Terrell and Waite, 1961; Waite and Terrell, 1961).

The last two studies offered a clue as to why, in some cases, delay may result in less efficient learning. In these two studies, 5- and 6-year-olds were presented simultaneous form and size discriminations, one problem was coupled with immediate reinforcement and the other with delayed reinforcement. The children seemed to lose interest in the problem involving delayed reinforcement. The

possibility that the detrimental effects of delayed reinforcement may be attributable to inattention resulting from boredom or frustration has been investigated in several subsequent studies. Fagan and Witvyl (1966) found that such effects could be eliminated if the Ss were instructed to look at the source of reinforcement during the period of delay. Maintaining attention to the source of reinforcement presumably made it less likely that interfering responses would be learned during the delay period. Other Ss receiving delayed reward but no instructions about what to do during the delay period performed more poorly than a group receiving immediate reinforcement. Further support for the importance of the delay period as a time when interfering—or facilitating—responses can be made was found by Wright and Smothergill (1967). Immediate reinforcement was less effective than delayed reinforcement if active observing behavior occurred during the delay period.

The frequent failure to find significant effects of delay of reward with children thus may be a result of children's ability to maintain appropriate orienting responses during the period of delay—an incomparably more difficult feat for animals. Another related factor may be children's ability to bridge the period of delay with forms of self-instruction or mediating responses. A tendency for younger children to be more strongly affected in a negative manner by delay than older children has been noted by Terrell (1965), which may indicate that younger, less verbally facile children are less likely to make such responses spontaneously than are older children.

Blackbill and her associates have demonstrated a secondary gain from delay of reinforcement. In a series of studies they found no significant effects of delay of reinforcement on acquisition but consistent facilitating effects on retention of a discrimination. For example, Blackbill (1964) attempted to determine whether the introduction of a distracting task during the delay period would diminish the effects of delay on retention. The Ss were required to copy numbers during the 10-second delay between response and reinforcement. The immediately reinforced Ss were also required to copy numbers, but after the reinforcement had been delivered.

A 20-second intertrial interval was used for all groups. In contrast to previous findings, the Ss learned a series of 18 two-choice discriminations more slowly with immediate than with delayed reinforcement. Surprisingly, the delay group performed at the same level during acquisition trials as another delay group, which did not perform an intervening task. As was found in the previous studies, significantly greater numbers of trials were required to relearn the discrimination 1 or 8 days after acquisition by the Ss who received immediate reinforcement during training than by those for whom reinforcement had been delayed. Despite the consistency of this finding across a number of studies, its explication awaits additional research.

Response Biases

The discrimination learning situation may elicit response biases in children which are important considerations in evaluating performance. In a two-choice task with undiscriminable stimuli and nondifferential reward, Jeffrey and Cohen (1965) reported that 3-year-olds tend to persevere in making position responses, whereas 4-year-olds tend to alternate their choices between the stimuli. Schusterman (1963) has reported similar effects for 3- and 5-year-olds, but 10-year-olds were found to demonstrate neither response pattern. Rieber (1966) repeated the Jeffrey and Cohen study with 7- and 9-year-old Ss. Nearly three-fourths of the Ss showed alternating behavior when either response was consistently reinforced, but the number of alternations dropped significantly under schedules of nondifferential partial reinforcement. Considering the three studies, it appears that a preference for alternation is present at age 4, persists through age 8, and drops out by age 10.

Stevenson and Wen (1961) investigated the effect of initial reinforcement or nonreinforcement of response in a three-choice spatial discrimination task on the tendency to repeat the response on the subsequent trial. At age 3 over 80% of the Ss repeated the response that had led to reinforcement on the previous trial, but by age 9 fewer than 30% did so. When the initial response was not reinforced, fewer than 50% of the 3-year-olds and practically none of the 5-, 7-, and 9-year-olds included in the study repeated the response.

Greene (1964) reported similar results in a study of preschool and kindergarten children. The Ss were presented varying numbers of trials in a two-choice color discrimination problem before a third, novel stimulus was introduced. On trial 2 nearly 70% of the Ss shifted their response to the stimulus that was not chosen on trial 1. A similar percentage of Ss chose the novel stimulus when it was introduced, and the tendency to shift to this stimulus was not influenced significantly by the number of prior trials with the two discriminative stimuli. In another study using the same problem, Greene and Terrell (1964) found that over 70% of the Ss in grades 1, 3, and 5 shifted their response on trial 2 to the stimulus that had not been chosen on the previous trial. In contrast to the Stevenson and Wen study, however, no differences in this tendency were found across grades, and a greater tendency was found to shift response after reinforcement than after nonreinforcement. The bases for the discrepancies are not clear.

These are paradoxical results for a reinforcement theorist. Reinforcement does not increase the tendency of older children to repeat a response, it has the opposite effect of increasing the likelihood that an alternative response will be made. Three-year-olds, however, are a different matter, they do behave as they should according to traditional concepts of reinforcement. This, it will be seen, is the first of many instances where the behavior of preschool children, but not of older Ss, conforms to reinforcement theory. The interpretation of the performance of the older Ss appears to require the introduction of new concepts and several alternatives have been offered. Children may switch their response to the new stimulus out of curiosity to discover what would happen if it were chosen, children may have learned to expect that adults are unlikely to reinforce a particular choice consistently, or children may wish to be "fair" and give each alternative an equal chance of being selected. At present, it is impossible to decide whether one of these alternative explanations is more relevant than the others.

Developmental Studies

Other than in the studies reviewed, there has been little interest in studying discrimination learning at different ages. At first, such

studies would seem to be unproductive ventures, for there is little obvious basis for predicting anything other than an improvement in performance with increasing age. But several developmental studies have reported quite unexpected results.

Stevenson, Iscoe, and McConnell (1955) presented a two-choice size discrimination to Ss at six age levels between the preschool and college years. As expected, performance improved consistently between ages 4 and 11, with the 11-year-olds learning the problem in a very small number of trials. After this, however, performance became increasingly inefficient, the frequency of correct response decreased consistently across the next three age levels, ending with the college Ss performing at approximately the same level as the 4-year-olds. A curvilinear relation between age and rate of learning also was found in a study by Wen and Stevenson (1959), where Ss between the ages of 3 and 9 were presented a serial discrimination task involving drawings of five pairs of common objects. Learning was more rapid for 5- than for 3-year-olds, but both 7- and 9-year-olds performed less adequately than the 5-year-olds.

How can such odd results be interpreted? The older Ss in these studies appeared to be unable to accept the fact that the problems were as simple as they actually were. Consequently, they developed complex hypotheses about their solution that hindered the development of the more simple, correct response. The expectations that children have about the level of difficulty of the problem may lead to poor performance unless the expectations are roughly in concordance with the actual level of difficulty.

A second set of developmental studies explored changes in the ease of learning a relation between two members of a pair of stimuli. The discrimination of relations between sets of stimuli should be more difficult than the discrimination of common elements, if it is assumed that the former requires some type of higher order abstracting ability. Graham, Ernhart, Craft, and Berman (1964) found the opposite to occur. Children between the ages of 2 and 4½ years were presented pairs of stimuli, each pair consisting of a common stimulus and a second stimulus larger or smaller than the first. For some Ss, response to the relation between the stimuli

was reinforced (*i.e.*, the larger stimulus in each pair was reinforced) and for other Ss the stimulus that was common across the pairs was reinforced. Learning the absolute discrimination was harder at all ages, but the difficulty decreased with increasing age. Performance on the relational problem was maximal by the age of 3.

Further evidence of young children's ability to respond to relations between stimuli before the age at which they normally demonstrate relational concepts in other ways was found by Berman and Graham (1964). Preschool children were presented two squares, both of which were reinforced on a single trial. On the second trial, one of the first-trial stimuli and a new stimulus were presented. On trial 2 the children chose the stimulus of the same relative size more often than they chose the alternative stimulus. Hence the ability to respond to relations between stimuli is a primitive form of behavior that does not require verbal control.

Similar effects have been found for auditory discrimination (Riley, McKee, Bell, and Schwartz, 1967). First and third graders were instructed to make absolute or relative judgments concerning tones differing in loudness and pitch. The Ss followed instructions for amplitude better than for frequency, and Ss followed relative instructions better than absolute instructions. Children of these ages appeared to discriminate between amplitudes almost exclusively on a relational basis. Third graders performed better than first graders only when the discrimination trials were not preceded by pretraining with other stimuli and when the Ss were required to make either absolute or relative judgments, but not both. As the authors point out, however, a relational discrimination does not require Ss to remember relations among particular stimuli, but an absolute discrimination is dependent upon the retention of information about a specific stimulus. The relational discrimination may be a more primitive mode of response since it requires less differentiation of the specific attributes of the stimuli and is less dependent on memory.

LEARNING SET

There are many indications that experience with learning problems results in more effi-

cient learning of new problems. Some factors contributing to this improvement are the elimination of biases and other incorrect response tendencies, development of appropriate observing responses and increased attention to relevant cues, modification of expectancies concerning the difficulty of the problem, and acquisition of strategies for maximizing the information from each response. When the problems are all of the same type, positive transfer across learning tasks should be maximal. This is the case, for when Ss, both human and nonhuman, are given a series of two-choice discrimination problems, a point is reached where the correct response is learned in no more than one trial. The S has learned how to learn, or has developed what is called a learning set.

The first studies of learning set with children as Ss were aimed at determining whether children could form learning sets (they could) and whether brighter children formed learning sets more rapidly than duller children (they did). Learning sets are developed by children with great rapidity, for example, Reese (1965) found that only 17% of trial-2 responses were incorrect when 3- to 5-year-olds were required to learn a series of two-choice object discrimination problems. In another study (Ellis, Guadeau, and Pryor, 1962), only one problem was necessary for children to develop a learning set if this problem was learned to criterion. The correlation between MA and number of problems necessary to reach criterion of learning set has been found to vary between -50 and -60 for younger Ss (e.g., Koch and Meyer, 1959). Although there has been no rigorous investigation of the effects of type of stimulus on rate of acquiring learning set, it appears that the type of stimulus plays a less important role in the development of learning set in children than in lower animals.

Two of the most definitive studies of the role of MA and IQ on the development of learning sets have been reported by Harter (1965, 1967). In the first study, children at three levels of MA (5, 7, and 9) and three levels of IQ (70, 100, 130) were presented 10 four-trial problems a day until they reached a criterion of over 90% correct response on five successive problems. Significant differences in performance were associated with MA, IQ, and the interaction

between MA and IQ. Thus both level of intellectual functioning and rate of intellectual growth were significantly related to the ease of developing learning sets. The interaction reflects the greater differences in performance among the MA groups at IQ 70 than at the higher IQ levels and the greater differences between IQ groups at MA 5 than at MAs 7 and 9. The interaction of MA and IQ and the low relationship of MA with performance for the children over 8 years old probably is due partly to a ceiling effect resulting from the simplicity of the problems.

In the second study, Harter included two MA levels, $5\frac{1}{2}$ and $8\frac{1}{2}$, and three IQ levels, 65, 100, and 130. The findings were similar to those of the first study, indicating more rapid development of learning set at the higher levels of MA and IQ. In their pre-criterion performance, younger Ss employed response-set hypotheses, evident in position preferences and position alternations, whereas older Ss employed hypotheses contingent on the outcome of the prior response, such as win-stay, lose-shift. The latter types of hypothesis are, of course, more useful in solving the problems. Level of IQ was not clearly associated with different types of hypothesis. In addition, half of the Ss were tested under a standard, neutral condition and half were praised for correct response. The two conditions did not influence the performance of the higher MA Ss significantly, but performance of the lower MA Ss was higher in the praise condition. Motivational differences associated with intellectual level may play an important role in determining the rate at which a learning set will be formed.

The effects of varying the difficulty of successive problems on the acquisition and retention of learning set has been studied by Katz (1967). The Ss, preschool children from a culturally deprived population, were separated into average and low IQ groups (mean IQs of 102 and 84, respectively). The difficulty of the problems was increased by reducing the number of dimensions (shape, size, color) represented in geometric figures, in the easiest problems the stimuli differed on all three dimensions and in the most difficult problems they differed on only one dimension. In line with other results, groups given prior experience with object discrimination problems did better on three criterion

problems than did a group with no prior experience. Within the pretrained groups the sequence of relative difficulty of the training problems did not influence performance on the criterion problems. When the two IQ groups were considered separately, however, a significant effect was found for the low IQ Ss: a transition from easy to moderately difficult or from easy to difficult problems produced decrements in performance. A portion of the Ss were retested after 6 months. The Ss who had received prior training showed greater improvement across the test problems than did the control Ss, indicating that the improved performance was due to enhanced speed of learning rather than to better immediate memory.

ODDITY LEARNING

Discrimination learning problems can be made more difficult if S is required to choose the odd object from among a set, rather than one particular object. In studies of oddity learning, three or more objects are presented on each trial, one of the objects is dissimilar from the others. Since different sets of objects are used on successive trials, S must abstract the quality of "oddity" as the relevant basis for response. An even more difficult problem, a conditional oddity problem, can be constructed if additional cues are provided to indicate the dimension of oddity relevant on a particular trial. For example, the discriminative stimuli may differ in color and form. If they are presented in the presence of one cue, oddity in color is the relevant dimension, whereas in the presence of a second cue, oddity in form is the relevant dimension.

Several developmental studies of oddity learning have been reported. Gollin and Shuk (1966) presented children between the ages of 4 and 7 an oddity problem involving color. The percentage of Ss capable of reaching criterion within 54 trials increased from 42% for the 4-year-olds to 88% for the 6-year-olds. These levels of performance were somewhat higher than those found in an earlier, similar study by Lipsitt and Serunian (1963), but the pattern of changes across age was highly similar.

Hill (1965a) also found developmental changes in oddity learning between the ages of 4 and 12. All of the 12-year-olds, over

50% of the 6-year-olds, but only 10% of the 4-year-olds were capable of reaching criterion within 200 trials in a task involving objects that differed in shape and color. Hill also compared performance on the oddity problem with that found in a two-choice discrimination and in a conditional oddity problem. The object discrimination problem was easier than the oddity problem, and the conditional oddity problem was quite difficult. Since the Ss were presented at least two of the problems, transfer effects could be assessed. Negative transfer was found for 4-year-olds when they were given the discrimination task after the oddity problem, and positive transfer was found for 12-year-olds when they were given the conditional oddity problem after the other two problems.

In a direct investigation of possible sources of transfer, Hill (1965b) pretrained 4- and 6-year-olds with a two-choice object discrimination task or with pairs of stimuli identical or different in form and color. Following pretraining, the Ss were presented an oddity problem with a new set of objects that differed in form and color. No differential effects of the two types of pretraining were found for 4-year-olds, but the 6-year-olds benefited more from pretraining that emphasized the attributes of similarity and difference between pairs of objects than they did when they simply were given a discrimination task during pretraining.

The effects of the presence of irrelevant stimulus dimensions on oddity learning was investigated with 8- to 10-year-olds by Lubker and Spiker (1966). The stimuli were squares, triangles, and circles that were either white or black and large or small. When only one within-trial irrelevant cue (brightness) and one irrelevant between-trial cue (size) were present, learning to discriminate oddity of form did not differ from the case where there were no irrelevant within-trial cues but different between-trial cues. When, however, two irrelevant within-trial cues were present (*i.e.*, the stimuli differed in form, size, and brightness) learning was less efficient than when there were no irrelevant within-trial cues.

Two other variables that influence oddity learning are stress and the similarity of the stimuli (Lipsitt and Lolordo, 1963). Nine-year-olds were tested with three colors that

were either distinctive or similar, half were instructed there was a time pressure on their performance and half were given neutral instructions. Slower learning was found when the stimuli were similar than when they were distinctive, presumably because the similar stimuli aroused competing responses, which interfered with learning. The interaction between stress and task difficulty was also significant: learning was facilitated under stress when the stimuli were distinctive, but when the stimuli were similar stress had a deleterious effect on performance. In fact, the performance of the group given stress instructions and similar stimuli did not improve across 54 trials.

TRANSPPOSITION

In the initial phase of the transposition problem, Ss are trained to respond, for example, to the larger of two stimuli. In the second, test phase the smaller of the original pair is replaced by a third, still larger stimulus. Will S now choose the originally positive stimulus or will he choose the larger stimulus of the pair? The general finding that animals of different species and humans of different ages tend to choose the larger stimulus on the first test trial was used by the Gestalt psychologists to support the view that learning is a result of developing an understanding of the relations that exist among stimuli, rather than acquiring specific stimulus-response connections. How, otherwise, could one account for the fact that Ss select the stimulus in the test set that they had not encountered previously in preference to a stimulus that had been reinforced consistently? Spence (1937) proposed a model to handle this question. Spence assumed that the habit strength developed to the positive stimulus during training generalized to other stimuli along the same dimension, as did the inhibitory strength developed to the negative stimulus. By summing the excitatory and inhibitory tendencies algebraically at different points along the stimulus continuum, it is possible to predict that transposition will occur for "near" stimuli (stimuli near the training set) but not for "far" stimuli (stimuli further removed on the stimulus dimension). The second prediction is not in accord with a relational theory, and evidence of a decrease

in the incidence of transposition as the test stimuli become more remote from the training stimuli (the "distance effect") was interpreted as an indication of the greater power of a stimulus-response, or absolute theory.

Many studies of transposition have used children as Ss, but current interest in the problem can be traced to the publication of a study by Kuenne (1946). Kuenne assumed that different frequencies of transposition would be obtained, depending upon the Ss' linguistic competence. The performance of young children who cannot verbalize relations among stimuli should conform to the predictions of Spence and be similar to that of nonverbal organisms. Older children, however, who can verbalize a relation such as "larger than," should depend upon the verbal cues to guide their response and their performance should be less dependent upon the absolute characteristics of the test stimuli. Accordingly, it was predicted that younger Ss would show a distance effect, but that transposition would be maintained at a high level by older Ss even for remote stimuli.

In a study of the performance of Ss varying in mental age from 3 to 6 years, Kuenne found support for these predictions. Transposition remained at a high level across all MA levels for a "near" set of stimuli, but decreased consistently for a "far" set as MA decreased. Post-test questioning of the Ss indicated that the younger Ss were less capable of verbalizing the size relation that existed within the pairs of stimuli; none of the Ss at the 3-year level and nearly all at the 5- and 6-year levels were able to verbalize the principle either spontaneously or upon questioning. Kuenne's results were replicated shortly afterward by Alberts and Ehrenfreund (1951).

Subsequent studies have not consistently supported Kuenne's two-stage model. For example, Stevenson, Iscoe, and McConnell (1955) found no marked changes in the incidence of transposition between the pre-school and college years, and a distance effect was not obtained by Stevenson and Iscoe (1955) for the first-trial performance of retarded Ss, who presumably were preverbal in the sense that only 3 of the 44 Ss could verbalize the basis for solving the problem. Totally discrepant findings have been re-

ported by Rudel (1958) The Ss, 21 to 45 months of age, were divided into preverbal and verbal groups according to their ability to pick out the "bigger" or "smaller" of a pair of squares at the completion of the testing session The Ss were trained on a size discrimination in which the larger stimulus was correct for half of the Ss and the smaller stimulus was correct for the other half Five sets of increasingly large stimuli were used in the test trials for different groups of Ss A U-shaped curve was obtained transposition decreased across the first three pairs of test stimuli but then increased for pairs 4 and 5 In addition, a significantly higher incidence of transposition was found when the smaller than when the larger in the training pair had been correct and there was no overall difference in the performance of the preverbal and verbal Ss Only the decrease in transposition found for pairs 1 to 3 by the preverbal Ss is in accord with Kuenne's model

One of the most difficult sets of results for the model to explain is that reported by Johnson and Zara (1960) The behavior of half of the Ss in this study conformed to the model, but that of the other half did not Two groups of Ss between the ages of 3 and 5 years were trained on a size-discrimination problem When only one pair of stimuli was presented on the training trials, as had been the case in the previous studies, a distance effect was found When, however, two pairs of training stimuli were used, the Ss transposed at a high level regardless of the distance between the training and test sets The gradients posited by Spence cannot account for such an effect, although the effect can be understood if it is assumed that (1) when the same relation exists in multiple sets of training stimuli Ss are more likely to discover the relevance of the relation between the stimuli for solution of the problem and (2) Ss are able to utilize such information on the test trials The results have been replicated by Sherman and Strunk (1964)

Additional discordant results have been reported by Hunter (1952) for 5-year-olds As in the preceding two studies, Ss were trained with more than one set of stimuli, but in this study the different sets were presented successively rather than simultaneously The procedure was rather complicated

Different combinations of stimuli were used with different groups, but all embodied the following type of training After Ss had learned to select the larger of two circles consistently, a new set of stimuli whose members were larger than the first set was presented When the larger of these two stimuli was selected consistently, trials were given with a third set whose positive member was the stimulus that had not been reinforced during the second phase and whose negative member was a blank card The last set was used to offset the inhibitory tendencies that would be predicted to develop during the second phase of training On the test trials a pair of stimuli was used whose members consisted of a stimulus larger than any of those used during training and a stimulus whose size was intermediate between the stimuli reinforced during the first two phases of training According to an absolute theory, the last stimulus should be chosen on the test trials, for its excitatory strength is postulated to be the sum of the generalized excitatory strengths derived from the training stimuli Any generalized inhibitory strength to this stimulus should have been eliminated by the third phase of training Thus the Ss should have chosen the smaller stimulus in the test set rather than the more distant, larger stimulus Nevertheless, over 80% of the Ss made a relational response Furthermore, when a similar procedure was followed in a second study with Ss whose mean age was 23 months, 80% of the Ss made a relational response on the test trials

The results of the preceding three studies indicate that training with multiple sets of stimuli is conducive to making a relative response, even when the training is devised so that it supposedly yields gradients that, according to Spence's model, should result in absolute responding

Another implication of the model was tested by Cole, Dent, Eguchi, Fujii, and Johnson (1964) Three-year-olds were trained with a "fading in" technique whereby the negative stimulus was represented initially by a thin line, which gradually evolved across the 30 training trials into a small square The positive stimulus, a larger square, was complete on all trials This technique made it very unlikely that the Ss would make errors and, consequently, that inhibitory tendencies

would be developed for the negative stimulus. In such a situation, the Ss did transpose to a significant degree.

Spence's model obviously is inadequate for predicting the behavior of young children in transposition tasks. Does the second aspect of Kuenne's developmental model fare any better? The results of a study by Marsh and Sherman (1966) indicate that it does not. The purpose of this study was to determine whether the frequency of transposition could be increased by instructing Ss about the relevant dimension and eliciting relevant verbalizations prior to each response. Two groups of Ss with mean ages of 3.2 and 4.6 years were trained with a pair of squares differing in both size and brightness. The two dimensions were relevant and redundant in that, for example, the large black square was positive and the small white square was negative. The Ss were tested with the previously positive stimulus and a new stimulus that differed in both size and brightness from the other member of the pair. No age differences in performance were found, and the youngest Ss for whom size was verbalized did not transpose above chance on the test trials. Those for whom brightness was verbalized tended to choose the previously positive stimulus. When the study was repeated with 2-year-olds, now including a group receiving no instructions, the incidence of transposition again was not significant, the Ss in all groups tended to choose the previously positive stimulus. Thus activation of a verbal response through instructions is not sufficient to insure that performance of the young child will be influenced significantly by such verbalization. McKee and Riley (1962) reported similar results for auditory transposition. Labeling of tones as "high" or "low" did not facilitate transposition along a pitch dimension.

A different approach was taken by Zeiler (1966) with 4- and 5-year-olds, all of whom could verbalize size relations. The area-ratios of the stimuli used in this study were either 1.96:1 or 1.4:1. A gradient similar to those found by Kuenne and by Alberts and Ehrenfreund for preverbal Ss appeared for the stimuli with the lower area-ratio, but a uniformly high level of transposition was found for the stimuli with the high area-ratio. It is possible therefore that the difficulty of the original discrimination, rather than the presence or ab-

sence of verbal mediation, may determine whether or not a distance effect will be found. Stimuli with a low area-ratio are more difficult to discriminate, and, as indicated earlier, the younger Ss in the two earlier studies required far greater numbers of trials to solve the original discrimination than did the older Ss. If the original problem is difficult, Ss may be more likely to develop a relational response than if the absolute characteristics of the training stimuli differ greatly.

The evidence appears to indicate, then, that such variables as stimulus conditions, characteristics of the Ss, and types of training will determine whether or not transposition occurs. Some studies support a relational interpretation, whereas some support an absolute interpretation. However, it may be inappropriate to attempt to categorize learning as either relational or absolute. Johnson and Bailey (1966) reported results from a very extensive study involving five training conditions, different numbers of training problems, and three age levels (kindergarten, fourth grade, and college Ss). Although the overall proportion of relational responses on the test trials was high (.73), the proportion varied widely, and systematically, across the various subgroups, depending upon the training conditions and the age of the Ss. For example, when kindergarten Ss were presented the stimuli successively and without opportunity for comparison, the proportion of relational responses was .29, but when the stimuli were presented successively and they could be compared, the proportion increased to .92. The results of this study are complex, but they indicate clearly it is possible to manipulate the incidence of absolute and relational responding by modifying the stimulus situation within a relatively restricted range.

The Intermediate-Size Problem

In addition to research on the two-stimulus problem, there has been a great deal of interest in the transposition of intermediate size. Researchers initially became interested in this problem because of the opposing predictions of the relational and absolute theories. According to relational theory, transposition of intermediate size should occur, according to absolute theory it should not. The basic assumptions of the absolute theory are the same as those previously discussed, but now there

are two gradients of inhibitory tendencies and one of excitatory tendencies. By summing the strengths of these tendencies along the relevant stimulus dimension, the net excitatory strength is found to be greatest for the stimulus nearest in size to the initially positive stimulus. Thus in tests of transposition one step removed (a set of stimuli consisting, for example, of the two larger members of the original set and a new, still larger stimulus), pre-verbal Ss are predicted to choose the previously positive stimulus, thereby making an absolute response.

One of the first investigations of the transposition of intermediate size was reported by Stevenson and Bitterman (1955), whose Ss were 4- to 6-year-olds, none of whom could relate the significance of middle-size to the solution of the problem. Test trials were conducted with sets of stimuli one and five steps removed from the training set. Transposition was found for stimuli one step removed, and a distance effect was obtained. There was a much lower incidence of transposition for stimuli five steps removed than for stimuli two steps removed. These results were interpreted as indicating that during training Ss had learned something about both the relations that existed among the stimuli and the region occupied by the training stimuli on the stimulus continuum. Hence transposition would be predicted to occur when the test set is near the training set but to decrease as test sets become increasingly dissimilar to the training set. A similar view had been suggested by Hunter (1954).

One implication of this position is that the probability Ss will transpose depends on the discriminability of the test set from the training set. If the training stimuli are highly similar, transposition is more likely to occur than if the stimuli are dissimilar, since discriminating between-set differences should be more difficult when within-set differences among the stimuli are small. Reese (1962) tested this hypothesis by using two sets of stimuli, with area-ratios 1:3:1 and 2:1. Transposition was found for all groups on a near test, but on a far test the preschool Ss transposed only when the area-ratio of the stimuli was small.

Another implication of the "discriminability" hypothesis is that transposition on far tests should occur if it is made clear to the Ss that the relation learned during training is ap-

plicable to a broad range of stimuli. Gonzales and Ross (1958) trained 4-year-olds with two sets of stimuli selected from opposite ends of a size continuum and tested the Ss on a set intermediate between the two training sets. Far transposition was found for the 4-year-old Ss with this procedure. Subsequent studies by Caron (1966) and by Beatty and Weir (1966) with 3- and 4-year-olds confirmed this finding and showed that the effect was dependent upon training with extreme sets of stimuli rather than upon multiple-set training, as might be suggested by the Johnson and Zarka (1960) results cited earlier. Two training problems were used in these studies, each involving two sets of stimuli. In one problem the sets were selected from one extreme on the size dimension, and in the other, one set was selected from each extreme. Only far tests of transposition were used. Of the 90 Ss in each of Caron's conditions, 25 transposed on the first test trial in the first condition and 55 in the second condition. In the Beatty and Weir study, 3 of 20 in the first condition, but 16 of 20 in the second condition transposed on the far test. None of the Ss in a third condition, which involved training on only one set of stimuli, transposed. The likelihood that Ss will transpose on far tests thus is increased if training encompasses extreme instances in the range of stimuli, but, in contrast to the results of two-stimulus problems, the incidence of transposition is not increased greatly by multiple-set training.

There is other evidence that the intermediate-size problem involves processes different from the two-stimulus problem. The S's ability to verbalize relative size was an important variable in the two-stimulus problem, but stimulus conditions appear to play a more important role in determining performance on the intermediate-size problem. Studies by Caron (1966), Reese (1961b, 1962), Reese and Fiero (1964), Rudel (1957), and Zeiler (1963a) found no relation between performance of Ss on test trials and their ability to verbalize the concept of middle-size. In another study (Reese, 1966) the experimenter named the correct or the incorrect stimuli for 3- to 5-year-old Ss during training, and a distance effect was found, even though this effect would not be expected when verbal mediation is possible. The incidence of transposition was higher, however, among Ss for whom the ex-

perimenters labeled the correct or incorrect stimuli than among Ss who received no directive instructions. The only other study in which differences were found among Ss who possessed the concept of middle-size and those who did not was reported by Caon (1967). First-trial choices on tests of transposition were equally high for both groups on near tests, but on a test six steps removed from the training stimuli, a greater number of the Ss who possessed the concept transposed. None of the studies offers any basis for determining why possessing labels for the stimuli exerts a significant effect on transposition in the two-stimulus problem but is only infrequently an important variable in the intermediate-size problem.

Zeiler (1963b) has presented a ratio theory of transposition that ignores the variable of level of conceptualization regarding intermediate size and derives its predictions solely on the basis of the characteristics of the stimuli present in the training and test situations. In many ways it is an attractive theory, for it offers a quantitative approach to the transposition problem, but experimental evidence has not given strong support to the predictions made. Basically, it is an application of Helson's (1964) theory of adaptation level. It is assumed that an adaptation level is established for the training trials which is a sum of the geometric mean of the values of the stimuli present and of a residual adaptation level derived from prior experience. The S learns to select a stimulus that has a particular ratio to the adaptation level. During the test trials, the S is predicted to choose the stimulus whose ratio to the adaptation level established upon the perception of the test stimuli is most similar to the ratio of the original positive stimulus to the training adaptation level. Zeiler (1963a, 1963b) presents a series of studies with children that seem to be in line with these predictions.

A critical response to Zeiler's work has been made by Riley, Sherman, and McKee (1966), who found it impossible to replicate certain of Zeiler's findings. One of Zeiler's (1963b) central experiments was repeated. A series of stimuli, 1 through 8, vary in size from small to large. During training, stimuli 1, 2, and 8 are presented to all Ss, with 2 being the positive stimulus. During testing, stimuli 1 and 2 are retained, but the third

member of the set may be stimulus 3, 4, 5, or 6. As the largest test stimulus decreased in size, Zeiler found an increasing tendency for the Ss to choose stimulus 1. The most striking departure from what would be predicted from any other position was performance with test stimuli 1, 2, and 3. Riley, Sherman, and McKee repeated the study, using only this test set. Whereas Zeiler had found the largest number of Ss chose stimulus 1 on the test trial, in the replication study the largest number chose the stimulus of intermediate size. A second group of 4-year-olds was instructed to look carefully at all of the stimuli, on the assumption that the Zeiler effect might depend upon S's attending to all of the stimuli. Again, the largest number of Ss chose the stimulus of intermediate size. Additional groups either were instructed to find the middle-sized stimulus, were told that the reward would always be under a particular square, or were told to find the one that fitted the board. The third instruction was meaningful, for strips had been pasted on the stimulus tray of the same width as the stimulus of intermediate size. Relative choices on the test trial were more frequent for Ss given the first set of instructions, but when the instructions emphasized the absolute characteristics of the stimuli, a preponderance of absolute choices was made. The issues are not settled, for Zeiler (1966) has responded by pointing out other studies in which the results were in line with adaptation level theory, but, nevertheless, concluded that "because of the growing catalog of situational variables that cause absolute learning, the ratio theory is also unconvincing" (p. 260).

What is left from the studies of transposition, then, is a large amount of data in search of a theory. Transposition has been discussed in some detail because it is one of the most thoroughly explored problems in experimental studies of children's learning and because the data demonstrate with awesome vividness the complexity of the learning process in even very young children. There is little question that theoretical analyses capable of handling data derived from lower animals are incomplete and inadequate for predicting results from studies with children. Relational theories, absolute theories, discriminability theories, and even mediation and ratio theories may provide satisfactory accounts for portions

of the data, but new approaches, especially those emphasizing perceptual and verbal processes and their interaction with developmental level, will be necessary for a more comprehensive and satisfactory analysis of children's performance

REVERSAL AND NONREVERSAL SHIFTS

One case of transfer of training is transposition, in which transfer is assessed with sets of stimuli differing on a single stimulus dimension and bearing the same within-set relationship. Two other types of transfer problem that have captured a great deal of interest are reversal and nonreversal shifts, where Ss are trained with a set or sets of stimuli which differ in at least one dimension and are tested with sets that require Ss to shift their responses either to a second value of the previously relevant dimension or to a previously irrelevant dimension. As in the studies of transposition, the research has tended to be developmental and the role of language has received special attention. Much of the research on shift behavior with children was stimulated by a series of studies published by T. and H. Kendler and their associates. The basic paradigm used in the studies and the predictions made from the stimulus-response and mediation theory espoused by the Kendlers have been as follows:

For example, if a subject is initially trained on stimuli that differ simultaneously in brightness (black vs. white) and size (large vs. small) by being rewarded to responses to black regardless of size, a reversal shift would consist of learning to respond to white, and a nonreversal shift would consist of learning to respond to small. Comparisons between these two types of shifts are of particular interest because theories based on single-unit versus mediated S-R connections yield opposed predictions about their relative efficiency. A single-unit theory assumes a direct association between the external stimulus and the overt response and would predict a reversal shift to be more difficult than a nonreversal shift. This is because reversal shift requires the replacement of a response that has previously been consistently reinforced with a response that has previously been consistently extinguished. In a nonreversal

shift previous training has reinforced responses to the newly positive and negative stimuli equally often. Strengthening one of these associations does not require as much extinction of its competitor as in a reversal shift and should, therefore, be acquired more easily.

A theory that includes a mediating link (or links) between the external stimulus and the overt response leads to a different prediction. The mediating link is conceived of as a perceptual or verbal response, often covert, to the relevant dimension, which produces cues that elicit the overt response. In a reversal shift, the initial dimension maintains its relevance, hence, so does the mediated response. Only the overt response needs to be changed, and since the experimental situation provides only one alternative overt response, the problem presents no great difficulty. In a nonreversal shift the previously acquired mediation is no longer relevant, consequently both the mediating and overt response must be replaced, making the task more difficult than a reversal shift. It is therefore to be expected that for subjects who mediate, a reversal shift will be acquired more easily than a nonreversal shift (Kendler, 1963, pp. 35-36).

Earlier research had demonstrated that reversal shifts are more difficult for lower animals but nonreversal shifts are more difficult for human adults. Research with children was undertaken to determine whether a transition period might be found during childhood, before which children's performance would be similar to that of lower animals and after which children would perform in the fashion of adults. In an initial study (Kendler and Kendler, 1959), 5- and 6-year-olds were used as Ss. Overall, the children did not perform more poorly on one type of shift than the other, apparently contradicting the predictions made from both the single-unit and mediational positions. However, when the Ss were separated according to the ease with which they had learned the initial discrimination (above and below the median number of training trials), slow learners were found to learn the reversal shift more slowly than the nonreversal shift, whereas fast learners learned the reversal shift more rapidly than the nonreversal shift. The de-

duction was made that the fast learners had approached the task with verbal labels, which facilitated both original learning and reversal performance, whereas the slow learners had not

Shifting the age level downward should provide some clarification of the first study, for with 3- to 5-year-olds, who presumably are less likely to utilize verbal mediators, reversal learning should be more difficult than nonreversal learning. This was found to be true (Kendler, Kendler, and Wells, 1960). There was negative transfer from the training trials for a reversal shift but positive transfer for a nonreversal shift. The impact of the results is weakened, however, by the fact that Ss who were required to verbalize the basis of response during the terminal phase of the training trials performed no differently from those who were not required to verbalize, even though the use of verbal labels had been assumed to be helpful in reversal learning. The authors were forced to conclude that at this stage "verbal responses, though available, do not readily mediate between external stimuli and overt responses, but rather form parallel connections with little or no interaction" (p. 87).

Relevant verbalization also failed to produce faster reversal learning with 4- and 7-year-old Ss in a subsequent study (Kendler and Kendler, 1961). Verbalization exerted a significant influence on performance only when Ss were required to use irrelevant verbalizations during training (by labeling the irrelevant cue), and even then interference was found only in the performance of the older Ss. An unsystematic relation between verbalization and performance was evident in the performance of kindergarten Ss in a later study (Kendler, 1964), where Ss were told the basis for correct response and required to verbalize this prior to making each choice during the training trials. When the reinforcement contingencies were reversed, many Ss continued to verbalize the previously appropriate statement—while making the opposite choice from that embodied in their verbalizations!

The "optional shift" technique has been used to provide an indication of S's tendency to use reversal or nonreversal modes of response (Kendler, Kendler, and Learnard, 1962). Optional shift studies are conducted

in three phases. During initial training Ss are presented two pairs of stimuli whose members differ in size and brightness. One attribute of one dimension is reinforced, for example, black. One pair of the original stimuli is retained in a second phase, but white is now reinforced. Since in this example the white stimulus may also be the small stimulus, Ss could be learning to respond in the second phase on the basis of brightness (reversal shift) or size (nonreversal shift). A test then is conducted with the pair of stimuli used in the second phase and an additional pair of stimuli including, say, a large white stimulus and a small black stimulus. Choices of either of the latter stimuli are reinforced. If S chooses the white stimulus of the second pair on 8 of the 10 test trials he is classified as having shown a reversal shift, and if he chooses the black (small) stimulus he is classified as having shown a nonreversal shift. Five age levels were sampled: the mean ages were 3, 4, 6, 8, and 10 years. The percentage of Ss demonstrating reversal shifts increased with increasing age, as was predicted, but contrary to the predictions, the percentage of Ss demonstrating nonreversal shifts did not change. Rather, a decrease was found in the percentage of Ss responding in an inconsistent fashion.

The technique was used by Kendler (1964) with kindergarten children in a study of the effects of verbalization on performance. The proportion of Ss demonstrating reversal shifts was higher among Ss who were required to verbalize the basis of their response than among those who were not required to verbalize. As indicated previously, some of the Ss in the second phase continued to verbalize the response that was appropriate to the first phase but was now inappropriate. When the study was repeated and only relevant verbalization was permitted in the second phase, the incidence of reversal shifts was higher in the verbalizing than in the nonverbalizing groups—but only when brightness was the initially relevant dimension. When it was shape, there was no significant difference between the verbalizers and the nonverbalizers. (In this, as in all of the studies, the training conditions were counterbalanced so that each attribute of each dimension was relevant for one-fourth of the Ss.)

Since rate of learning was correlated with

the frequency of reversal shifts, it is possible that the results may be attributable to the number of training trials, rather than to the operation of verbal mediation. To determine whether larger amounts of training would produce a lower incidence of reversal learning, Kendler and Kendler (1966) gave half of their Ss 16 and half 36 training trials on the original discrimination. Within this range, there was no significant effect of increasing the number of training trials. Nine-year-old Ss did, however, make more optional reversals than did 4-year-olds.

The work of the Kendlers is central, but it comprises only a small portion of the research on reversal-nonreversal shifts. Scores of studies have been published, researchers have been stimulated both by the Kendlers' work and by the work of others on the role of attention in discrimination learning (Mackintosh, 1965; Sutherland, 1964; Zeaman and House, 1963). As more and more data have come in, theoretical notions about reversal-nonreversal problems have met the same fate as the early ideas about transposition: the problems have proved to be so complex that none of the theories is capable of handling the essential results. Each can incorporate part, but conditions can be rearranged easily so that quite different results are obtained. There were enough hints in the equivocal findings in much of the Kendlers' own research to indicate that later studies would topple some of the central units in the structure they had built. It appears that theories about children's learning must be judged effective if they produce sufficient data to insure their own demise! This would be a depressing fate if it were not also evident that there has been progress, if progress is viewed as the ability to ask increasingly sophisticated questions.

The research on the effects of overtraining on reversal learning is a good example of the transformations that occur when the studies start by asking a seemingly simple question. The effects of overtraining have been investigated extensively with animals, and generally overtraining has been found to facilitate reversal learning (Spelting, 1965). The results from a number of studies of object discriminations with children reached the same conclusion (Cross and Tyler, 1966; Eimas, 1966b; Furth and Youniss, 1964;

Marsh, 1964; Tighe and Tighe, 1966; Youniss and Furth, 1964a, 1964b, 1965). In spatial discriminations, however, overtraining had no effect or a detrimental effect on reversal learning (Eimas, 1966b; Stevenson and Weir, 1959a; Youniss and Furth, 1964b), but, as was found in the last study, the addition of irrelevant, nonspatial cues may result in a facilitative effect of overtraining in spatial discriminations. Overtraining also facilitates the learning of intradimensional shifts, where new stimuli from the same relevant dimension are substituted for the training stimuli (Eimas, 1966a; Furth and Youniss, 1964; Heal, 1966). On the other hand, overtraining has been found to have variable effects on the rate of learning extradimensional shifts, where the second set of stimuli is from a new stimulus dimension. In general, then, overtraining increases the ease of learning a reversal or intradimensional shift, thereby producing the same effect found with the introduction of verbal mediation. Such a conclusion, however, is subject to several qualifications.

Gollin (1964) found that although overtraining facilitated reversal performance of 4½- to 5½-year-olds, it had a detrimental effect on the performance of 3½- to 4½-year-olds. The facilitative effect of overtraining also was restricted to the older Ss in a study of 3- and 4-year-olds by Tighe and Tighe (1966). In addition, the effects in the last study were dependent upon the stimulus dimension relevant during original learning. Practically all Ss for whom the relevant dimension was height reversed without overtraining, but when diagonal and vertical stripes were the relevant dimension, practically none of the Ss reversed without overtraining. After overtraining, the 4-year-olds in the latter group showed significantly more reversals, but there was no change in the performance of the 3-year-olds. The frequency of reversal shifts by 8- and 10-year-olds also has been found to differ, depending upon the dimension that was relevant during the training trials (Eimas, 1967). The frequency of reversal shifts was greater when the relevant dimension was size than when it was brightness. Thus the frequency of reversal shifts may depend upon the saliency of the stimuli and overtraining may interact

with saliency of stimuli and age in its effects on reversal learning

Jeffrey (1965) has reported a study that shows how a modest change in the testing procedure can produce results that have a destructive effect on any theory that postulates changes with age in the ease of reversal learning. The study included 4-, 6-, and 8-year-olds and college students. The Ss were trained on a color discrimination and after reaching criterion the previously nonreinforced stimulus was now reinforced. In addition to changing the reinforcement contingencies, the form of the stimuli was changed from circles to squares. With this procedure, there were no developmental changes in ease of reversal learning. Such results may be interpreted as indicating that young children's difficulty in reversal learning may be due to a difficulty in abstracting a single common dimension among the stimuli rather than to a lack of verbal mediation. Changing one aspect of the cues between the training and test trials apparently emphasized a commonality between the two sets of trials that otherwise would have been difficult for the younger Ss to recognize.

An additional feature of Eimas' (1967) study should be discussed, since it introduced another variable that interacts with overtraining in influencing reversal performance. The Ss were trained in the "optional shift" technique, half with a constant irrelevant dimension, and half with a variable irrelevant dimension. More reversal shifts were made by the latter than by the former Ss. Further, overtraining increased the frequency of reversal shifts following variable irrelevant training but decreased the frequency following constant irrelevant training. The results are interpreted according to the two-stage attention theory of Zeaman and House (1963), summarized by Eimas as follows:

According to this model, discrimination learning requires the acquisition of a chain of two responses, the first a mediating attention response to the relevant stimulus dimension, and the second, an instrumental choice response to one of the outputs of the attention response—the positive discriminandum. Furthermore, during original learning, overtraining is assumed to increase the probability of attending to the relevant dimension

without differentially affecting instrumental habits, at least to any considerable degree. A major assumption of the model, related to transfer-of-discrimination learning, is that both members of the response chain transfer across problems, provided that other stimulus arrangements or dimensions that function to divert the locus of attention from the previously relevant dimension are not introduced (Eimas, 1967, p. 338).

The introduction of the novel stimuli on the shift trials is assumed to constitute a source of diversion of attention, with maximal effects occurring following overtraining on a constant irrelevant dimension. The incidence of reversal shifts is assumed to be decreased after overtraining with constant irrelevant stimuli because of S's heightened tendency to respond to the new cues introduced on the shift trials. The high incidence of reversals without overtraining with variable irrelevant stimuli is interpreted as indicating that attention was maintained toward the originally relevant dimension, despite the fact that only one of the original pairs of cues was retained in the shift trials.

These and other studies provide information about the Kendleis' notions about the effects of verbal mediation on reversal. According to the Kendleis, following the attainment of criterion on the first task, preschool Ss should learn a nonreversal shift more rapidly than a reversal shift, but older Ss should learn the reversal shift more rapidly. Evidence in support of the first prediction was found in studies by Maish (1966) and Saravo (1967). There was no difference between the two types of shifts by the preschool Ss tested by Cobb and Price (1966). The second prediction also has received some support. Reversal shifts were learned more easily than nonreversal shifts by elementary school Ss in a study by Saravo (1967) when there were two or more dimensions varying simultaneously, and in a study by Sanders, Ross, and Heal (1965). No shift differences were found by Youniss and Fuith (1965) for Ss of these ages.

Similar predictions would be made for intradimensional shifts. An intradimensional shift should be learned more rapidly by older Ss than an extradimensional shift, for the Ss should find it more difficult to adopt a new

mediator, as would be necessary in the extradimensional shift, than to continue to apply the old mediator with new specific designations, as would be necessary in the intradimensional shift. The studies by Emas (1966a), Furth and Youniss (1964), and Heal (1966) support such a deduction. Similar results were found for kindergarten Ss in a study by Triabasso, Deutsch, and Gelman (1966) when the stimuli were objects differing in color and shape, but the two types of shifts were of equivalent difficulty when the stimuli were patterns. More rapid learning of intradimensional shifts was found by Dickerson (1966) for preschool Ss, who, according to the predictions, should learn the extradimensional shift more easily. The methodology of this study has been criticized by Tighe and Tighe (1967), who found that if 4-year-olds are trained in a fashion comparable to that used in the other studies, extradimensional shifts were learned more rapidly than intradimensional shifts.

The majority of the results tend to be in line with the predictions that age—and presumably level of verbal facility—interacts with type of shift. When verbalization is directly manipulated, however, the results turn out to be more elusive. The results of Silverman (1966) offer clear support for the facilitative effects of verbalization, for 3- and 4-, as well as 7- and 8-year-olds, learned a reversal shift more rapidly when they were required to verbalize the relevant dimension during training than when they were not. No overall facilitating effects were reported by Morse and Shepp (1967) when kindergarten and first-grade Ss were required to verbalize during the training trials. Among the intradimensional shift Ss, however, those who spontaneously continued to verbalize during the shift problem learned more rapidly than did those who abandoned verbalization after the training trials. For the older Ss, verbalization impeded the learning of extradimensional shift problems. Unexpectedly, the kindergarten Ss who verbalized during the training period learned both types of problems more slowly than did those who did not verbalize.

Blank (1966), who informed half of her preschool Ss of the solution to the training problem, found that such information did not help Ss significantly on a reversal problem,

for their performance was similar to that of groups for whom the correct responses were not labeled. Similarly, Cobb and Pice (1966) found no differences in the performances of preschool Ss who were given pretraining in learning relevant or irrelevant labels for the discriminative stimuli. Whatever the ultimate resolution of the sources of discrepancies among these studies, it is obvious that verbalization does not necessarily result in more effective learning of reversal and intradimensional shift problems.

One of the incidental results of a number of studies is the finding that the ease of making a reversal shift differs, depending upon the characteristics of the stimulus dimension that was relevant during training. Smiley and Weir (1966) investigated this problem directly by selecting color and form, dimensions for which Ss were known to have different preferences. The optional shift technique was used with kindergarten children. Prior to being presented the training problem, the Ss were given two series of trials on the basis of which they could be classified as being color or form dominant. During the training trials, either the dominant or nondominant dimension was reinforced. In the test series, a reversal shift was shown by 25 of the 32 Ss for whom the dominant dimension had been correct but only 8 of the 32 Ss for whom the nondominant dimension had been correct. In contrast to earlier findings, learning speed was not related to the incidence of reversal shifts but was significantly faster for Ss whose preferred dimension had been reinforced. There is a strong suggestion in these results that both rate of learning and frequency of reversal shifts may be a function of dimensional dominance rather than the operation of mediators, such that both speed of learning and frequency of reversals are increased if there is a fortuitous assignment of Ss to the condition in which their preferred dimension is reinforced.

Prior experience in differentiating the critical differences among the training stimuli has been found to decrease the number of trials required to learn a reversal shift (Tighe, 1965). The Ss who were given pretraining in making same-different judgments with the training stimuli learned a reversal shift more rapidly than did Ss who were given irrelevant pretraining in a control group or who were

presented a nonreversal shift. Another important and related variable has been isolated by Johnson and White (1967) in a study of 6- and 7-year-olds. Some of the Ss were pretrained with problems involving the ordering of stimuli on a dimension. Those above the median in performance on these tests made significantly fewer errors in the reversal problem than did those below the median. Thus reversal shifts are more likely to occur when the Ss had a more highly developed concept of dimensionality. A final study of pretraining by Vaughter and Cross (1965) found that prior experience with both stimuli used in a reversal task produced superior performance to that found when the experience was limited to one of the stimuli or when no preliminary experience was given.

A complex but elucidating study by Mumbauer and Odom (1967) assessed the roles of verbalization, overtraining, and dimensional preference on reversal, intradimensional, and extradimensional shift problems. Preschool Ss were tested with stimuli that differed in form and color. Initial learning was faster when the Ss were required to verbalize prior to responding and when Ss were tested with form as the relevant dimension. A significant interaction between verbalization and dimension indicated that verbalizing had no influence on the performance of Ss for whom form was the relevant dimension, but it facilitated performance when color was relevant.

In the shift trials, the main effects of verbalization, dimension, and type of shift were significant. Learning was faster for Ss who verbalized, for whom form was correct, and extradimensional shifts were harder to learn than the other two types of shift. Several significant interactions were obtained, and the general pattern in these interactions was for the performance of one of the groups to diverge from that of the other groups, which did not differ significantly. In the verbalization by overtraining interaction, Ss who had not verbalized and who were not overtrained required approximately twice as many trials to learn the discriminations as did the Ss in the other three groups. The divergent group in the significant verbalization-by-dimension interaction was the nonverbalizing-color Ss, in the overtraining-by-dimension interaction it was the nonovertrained-color Ss, and in

the shift-by-dimension interaction it was the extradimensional shift-color Ss. Possibly the most critical is the shift-by-dimension interaction, which indicated that only extradimensional shift Ss shifted to color differed significantly from the other groups. Differences in shift performance therefore appear to be a result of dimensional preferences rather than the operation of a mediation process. The interaction between verbalization and overtraining, indicate that these variables produce similar but noncumulative effects on shift performance.

These, then, are some of the more important studies on reversal shifts. The Kendleis' position has been emphasized, for their arguments and the research done to evaluate their predictions have had the greatest impact on research in this area. For obvious reasons, summary statements are difficult to make. Judging by the deluge of recent publications, the investigation of shift behavior has been considered to be important, primarily as a means of investigating the relation between the learning and the development of language. The hypothesis that performance between the preschool and elementary school years is increasingly influenced by verbal mediation at first appeared to be attractive in its simplicity and clarity. The studies do not necessarily invalidate the hypothesis, but performance that was assumed to be dependent upon mediation can occur without it, and stimulus variables and training procedures appear to exert at least as strong an influence on children's performance.

VERBAL MEDIATION

Several other studies have been concerned with developmental changes in verbal mediation. For example, changes in the use of verbal mediation have been posited to be the basis for developmental changes in double-alternation behavior (Pufall and Fuith, 1966). Developmental changes found in this problem closely correspond to those found for the other types of problem discussed. Four-year-olds had great difficulty in learning a LLRR pattern, but by age 6 the number of children acquiring the rule reached an asymptote not exceeded by children as old as 9.

Two periods in development are clearly defined: very early childhood, where relevant

language has not been acquired and hence the child is incapable of using verbal mediators, and adulthood, where behavior is largely under the control of verbal mediators. As has been pointed out by Reese (1962b), there is a period in early childhood where verbal responses do not seem to serve as mediators, even though the child is capable of using words. This "mediational deficiency" has been noted by Kuenne (1946), Kendler, Kendler, and Wells (1960), and Luria (1957). A recent article by Flavell, Beach, and Chinsky (1966) contrasts this view, which asserts that the child's verbalizations fail to influence his behavior, with a "production deficiency hypothesis," which proposes that "the younger child tends not to produce the relevant words in the first place, and this suffices to explain the apparent nonmediated characteristics of his overt task behavior. It is stipulated that he knows the relevant words and that he can and does produce them in some situations, his deficiency here consists solely in the fact that this particular task (or perhaps task-like situations in general) fails to elicit them" (p. 284).

In a test of this hypothesis, 5-, 8-, and 10-year-old Ss were presented a recall task, during which the experimenter lip-read by observing the child as he performed. Eighteen of the 20 youngest Ss, but only 3 of the 20 oldest Ss, showed no perceptible evidence of verbal rehearsal. Only 1 of the youngest Ss, but 13 of the oldest Ss, showed three or more instances of perceptible verbalization. No definitive interpretation of the mechanism underlying these changes was possible, but the results support a view that words may play a less important role in the behavior of young children, not because they are elicited and fail to be effective in directing behavior, but simply because they are not used. The relation of learning and language is bound to continue to be an important topic for further research.

PROBABILITY LEARNING

The structure of a probability learning task is similar to that of a discrimination learning task, except that the probability that response will lead to reinforcement is less than 1.00. The problem would be of little interest if children simply learned to make the response that led to the greatest frequency of rein-

forcement more slowly than they would if the response were reinforced consistently. But they do not. Further, research with children would add little to the body of information about probability learning if the proportion of times with which children ultimately selected the more frequently reinforcing stimulus reached an asymptotic level equal to the probability with which the response was reinforced, a result that is commonly found with adults. But, again, they do not. Children's performance changes with age and other variables interact with age in their influence on the choices children make.

The apparent simplicity of the probability learning task is deceptive. As shall be seen, the alteration of the schedule of reinforcement transforms a discrimination learning task into one that lies along the hazy boundary separating learning and problem solving. Since no solution yields consistent reinforcement, Ss are required to function as prediction-makers to a greater degree than in other learning problems. Because of this, the task has been used to delineate the role of more complex processes, such as sets and strategies, in children's performance at different ages. Although in many cases the studies have produced different and unreconciled results, the topics will be discussed in some detail because of the potential importance of many of the variables in the description of developmental changes in children's learning.

Most of the research has been conducted with two types of problems. In the two-choice problem, choices of one stimulus are reinforced, say, 75% of the time and choices of the other stimulus are reinforced 25% of the time. The schedule of reinforcement may be contingent upon response, as indicated in this example, or may be noncontingent on response in that reinforcement is potentially available but not necessarily obtained, for 75% of the choices of one stimulus and 25% of the choice of the other. A three-choice spatial problem also has been used in which choices of one position are reinforced, for example, 66 or 33% of the time, and choices of the other two positions are never reinforced.

Developmental Changes

Among the first questions asked in studies with children was whether their performance changed with age, and, if so, what trend these

changes might follow. An answer was obtained by Wen (1964a) who consolidated the data from a number of studies to produce a picture of changes among 3 to 18 years. The intermediate ages included 5-, 7-, 9-, 11-, and 15-year-olds. All had been tested with the three-choice problem under the same experimental conditions. Terminal levels of response, as indicated by the average numbers of responses made to the reinforced stimulus during the last 20 of the 80 trials presented, plotted according to age, produced a U-shaped function. With both 33 and 66% reinforcement, performance of the youngest and the oldest Ss exceeded that of Ss in the middle years of childhood. The rate at which these levels were approached was more rapid for the youngest than for the oldest Ss, whereas the performance of the middle groups tended to change very slowly or not at all. The general relations described by Weir have been found in the two-choice problem by Derks and Pac-lisanu (1967) for eight groups of Ss varying in age from 4 to 21 years, and portions of the curve have been replicated in other studies with both three-choice (Odom, 1967) and two-choice problems (Jones and Liverant, 1960).

Such age differences are interesting in themselves, but unless efforts are made to understand the underlying processes, the data constitute little more than another descriptive statement about normative changes in behavior. One bit of evidence that might indicate something about Ss' expectancies about the task may be obtained by determining the proportion of Ss at each age level who show maximizing behavior by the end of training, that is, the proportion of Ss who consistently choose the more frequently reinforcing stimulus. If Ss believe a solution yielding consistent reinforcement is possible, they should continue to vary their behavior in an effort to find such a solution. If, on the other hand, they do not have such expectancies, or if such expectancies have been extinguished, they should settle on a response that yields the greatest payoff. Wen (1964a) found that the proportion of Ss at each age level who show maximizing behavior in the three-choice problem followed a U-shaped function, indicating that the youngest Ss seemingly did not tend to have such expectancies and the oldest Ss apparently gave up such expectancies when they

found they were incapable of obtaining consistent reinforcement.

Another indication of the strategies employed by the Ss is the proportion of Ss who follow a simple LMR or RML spatial pattern of responses. Now, an inverted U-shaped function was obtained. Children between ages 7 and 10 employed these patterns with a high frequency, whereas both the youngest and oldest Ss used them less often. When Wen plotted the number of alternation patterns obtained in studies using a two-choice problem, an inverted U-shaped function again was found. It was suggested, in accounting for the frequent use of simple stereotyped patterns by the middle-aged child, that "the 7- to 10-year-old is at a point in development where his ability to generate complex hypotheses and employ complex search strategies is growing at a faster pace than his information-processing ability" (Wen, 1964a, p. 481). A more detailed discussion of this point will be made later.

A final analysis examined the effects of reinforcement and nonreinforcement on the Ss' tendencies to repeat a response. The youngest Ss were more likely to repeat a response, regardless of whether it was correct or incorrect, and the older Ss tended to show a win-shift, lose-shift strategy. Again, the relation between incidence of response repetition and age was curvilinear, with the Ss between 7 and 15 years more likely to adopt the win-stay, lose-shift strategy. In summarizing these analyses, Weir concluded that the developmental changes in probability learning are a consequence of "differential growth of the ability to generate hypotheses and employ strategies and the ability to process information. Ss gain from their own responding" (Wen, 1964a, p. 473).

The possibility that level of performance in a probability learning task may depend upon Ss' expectancies for reinforcement was tested in a study by Stevenson and Zigler (1958). The finding of an initial study that the asymptotic level of response was higher for institutionalized retarded children than for noninstitutionalized normal children led to the hypothesis that the first group had learned from their everyday experience to expect lower degrees of success than had the latter Ss, thus making it easier for them to accept a solution that yielded only partial reinforcement.

ment In a second study, normal preschool Ss were given pretraining games in which they experienced either uniformly high or low degrees of success Following this, the Ss were presented the three-choice task with a 66-0-0% schedule of reinforcement The prediction that Ss who had experienced low degrees of success in the pretraining games would perform at a higher level than those who had experienced a high degree of success was supported

A subsequent study by Gruen and Zigler (1968) contrasted the performance of middle- and lower-class 6-year-olds It was assumed that lower-class children have a background of more frequent failure than middle-class children, thus, following the reasoning just outlined, lower-class Ss should show a higher frequency of response to the reinforcing stimulus than middle-class Ss The results supported this assumption Success and failure experiences also were provided in a pretraining period, but they had no overall effect on performance When, however, separate analyses were made according to social class, it was found that for the middle-class Ss, pretraining with low degrees of success increased the frequency of choices of the reinforcing stimulus over that found following pretraining with high degrees of success The performance of the lower-class Ss was not influenced by pretraining The short-term manipulation of success appeared to be insufficient to overcome the expectancies of the lower-class Ss regarding their potential for success

Similar results were obtained by Odom (1967) in a study of 5-, 6-, and 10-year-old middle- and lower-class children Lower-class Ss made a significantly higher frequency of response to the reinforced stimulus than did middle-class Ss Lower-class Ss tended to make fewer pattern responses than middle-class Ss in both this and the previous study, which may indicate that the middle-class Ss demonstrated a higher level of cognitive development In neither study, however, was there a significant within-group relation between IQ and frequency of correct response

One of the arguments made by Weir (1964a) was that, unlike younger Ss, Ss between the ages of 9 and 12 are able to develop patterned response strategies in the probability learning task, but, unlike still older Ss, they are unable to reject these simple strategies if

they do not pay off consistently Weir suggested that inadequate memory of past events and their outcome is responsible for such behavior This possibility was investigated (Weir, 1967) by providing children with a memory-aid The Ss were 6- and 9-year-olds and adults, half tested with a memory-aid and half without In the memory condition the Ss were given a board in which pegs could be inserted to mark the response (LMR) just made and its outcome There was a significant interaction between condition and age the performance of the adult Ss was not influenced by the memory-aid, the performance of the 9-year-olds, as predicted, was higher with the memory-aid than without it, and the performance of the 6-year-olds was lower with the memory aid, apparently because they failed to understand its use and it consequently became an irrelevant task that disrupted performance The results of a second study with 5- and 9-year-olds and adults revealed that the memory-aid had other functions than merely indicating the locus of reinforcement When three containers, each located below the response button, were used, performance did not differ from that found with only one central container This result was not unexpected, for in previous studies, all of which used only one central container, Ss usually were able to identify the locus of reinforcement, despite the fact that they failed to select it consistently

The results of several additional developmental studies can be noted briefly The only exception to the previously discussed developmental changes in performance was found by Craig and Myers (1963) Kindergarten Ss performed at a lower level than fourth and eighth graders in a two-choice problem The use of a noncontingent schedule may account for the different results, but why this should be so is not clear Kessen and Kessen (1961) contrasted the behavior of younger and older Ss, with median ages of 3 ½ and 4 ½ years, in a two-choice problem where the probabilities of reinforcement changed in the middle of the experiment The younger Ss showed a greater reluctance to give up a rule that had previously been established and continued to respond in the second period on the basis of the schedule that had been in effect during the first period The older Ss, however, were able to modify their performance as a func-

tion of the changed probabilities. A related effect was found by Odom and Coon (1966). The LMR pattern of responses were reinforced in the three-choice problem for 90 trials, after which 20 extinction trials were presented. Six-year-olds were unable to give up the pattern response when it was no longer reinforced, but 11- and 19-year-olds showed clear evidence of extinction.

A variant of the probability learning task was used in a hide-and-seek game presented to Ss at ages 3 to 5, 7 to 8, and 10 to 12 years by Stevenson and Odom (1964). The *E* hid objects in three boxes so that the percentage of reinforcement for choices of the various boxes was 75, 25, or 0%. On alternate trials *S* hid objects, and *E* looked in *S*'s boxes according to a random schedule or a fixed schedule of 75-25-0% responses to the three boxes. Had the Ss adopted the optimal strategy for seeking by looking in the experimenter's 75% box and for hiding by placing their objects in the 0% box, a correlation between these two behaviors should have been obtained. There was no significant relation, however, between Ss' frequency of seeking in *E*'s 75% box and of hiding in the 0% box at any age level, indicating that the strategy for response differed according to *S*'s role as seeker or hider. As was found in the other tasks, however, Ss tended, with increasing age, to be more variable in their seeking behavior, to vary their responses more frequently after both reinforcement and nonreinforcement, to adopt patterned responses more frequently, and to utilize positional responses less frequently. In their hiding behavior Ss in the fixed condition did not relinquish the use of the 75% box, but they did show less variable behavior in this than in the random condition. The difference in performance between the two conditions was greater for the two oldest than for the youngest groups of Ss.

The study was repeated by Odom (1966a), but sex of *E* in relation to sex of *S* was varied. The *Es* hid trinkets in only one of the three boxes 66% of the time, and then seeking responses followed a random schedule. A significant sex of *E* by sex of *S* interaction was found with the 6-year-old Ss: boys made more correct responses than girls when *E* was a female, and girls made more correct responses than boys when *E* was a male. Thus the social setting, as well as the other variables that

have been discussed, may influence children's behavior in a probability learning task.

No sex differences in probability learning have been found, but the results of a study by Kass (1964) indicate that boys may be more likely to select situations that yield high or intermediate levels of reinforcement than are girls, who are more likely to select a situation that yields a low but consistent level of reinforcement. These results were derived from a study of children's choices of slot machines that were programmed so that each had an equal expected monetary return but a different probability of payoff.

Finally, Gratch (1964) studied possible differences in children's dependency upon adult approval of their performance in a probabilistic task at ages 6, 9, and 11 years. Two decks of cards differed in their construction so that one of two cards was more likely to appear in one deck than in the other. Teachers' ratings were obtained of the degree to which the children were dependent upon adult approval. The Ss were given practice on the two decks and then were asked whether or not they wished, in subsequent trials, to wager candy they had been given. The more dependent children showed a greater unwillingness to make such wagers than the less dependent children, but no differences in their actual guessing behavior were found. The older children evidenced more understanding of the structure of the task than the 6-year-olds, whose guesses were approximately the same for the two decks.

Incentive Effects

Incentive effects in probability learning generally have been studied on the assumption that effects found with no manifest incentives or with incentives of low value would be magnified when incentives were introduced. Blackbill, Kappy, and Stan (1962), for example, assumed that "Ss will maximize gain to the extent that there is something tangible to be gained by so doing" (p. 32). For each correct guess in a two-choice problem Ss were given 0, 1, 3, or 5 marbles which later could be turned in for a prize. The greatest difference in level of responding was attributable to the presence or absence of reward, but a decreasing hierarchy of "correct" responses (i.e., responses to the more frequently recurring stimulus) was found as the magnitude

of reward decreased. Several other studies obtained similar findings. Lower levels of asymptotic response were found by Siegel and Andrews (1962) with preschool Ss when the rewards were of low value than when they were of high value. Lewis, Wall, and Amonfreed (1963) found with 7-, but not 11-year-olds that the addition of supportive comments from the experimenter resulted in a significantly higher level of correct responding than occurred when Ss were given only information about the outcome of their previous guesses. The 6- and 7-year-olds in a study by Walters and Foote (1962) were more likely to make the correct response when they were given tokens that could be exchanged for prizes than when they were rewarded only with tokens. Finally, Offenbach (1964) found a higher level of performance when kindergarten and fourth grade Ss were reinforced with 1 or 3 marbles that later could be exchanged for a toy than when no marbles were given for correct response. The Ss were penalized for incorrect response by being required to return an equivalent number of marbles.

An interaction between incentive effects and social class was reported by Rosenhan (1966). Six-year-olds were praised for response to the more frequently reinforcing stimulus in a 70/30 two-choice problem or were given statements of disapproval following responses to the less frequently reinforced side. It was assumed that lower-class Ss are more sensitive to the responses of an adult than are middle-class children. The prediction that performance would be more strongly facilitated by praise in the lower than in the middle-class children was supported, as was the prediction that the performance of the lower-class children would be more disrupted by disapproval. The performance of middle-class children fell between the two extremes formed by the lower-class children and showed a tendency to be higher in the disapproval condition.

The results of a study by Stevenson and Wen (1959b) were in the opposite direction from those found in the preceding studies. When 5-year-olds were tested with the three-choice problem, higher levels of response were obtained with incentives of low value than with incentives of high value, when the reinforced choice yielded both 66 and 33% reinforcement. Although the results differ from those of the other studies, they are in line

with the assumption that incentives affect performance by determining the degree to which Ss will attempt to find a solution to the problem. If Ss persist in attempting to find a solution, they must continue to vary their behavior, thereby reducing the frequency with which they select the reinforcing stimulus. Paradoxically, then, the desire to obtain more incentives of high value should result in Ss' actually obtaining fewer reinforcements. Results similar to those found in this study were obtained by Das and Panda (1963).

Several studies have attempted to clarify the basis of these differences in incentive effects. Stevenson and Hoving (1964) noted that in addition to many procedural differences among the studies, the ages of the Ss also differed. Therefore a study was undertaken with 4-, 9-, 14-, and 20-year-olds with the three-choice problem and two levels of incentive. A curvilinear relation between frequency of correct response and age was obtained, and the interaction between age and level of incentive was significant. The results of the Stevenson and Wen (1959b) study were replicated for the 4-year-olds. For the two intermediate ages, the level of response of the high incentive group was below that of the low incentive group. Level of incentive did not differentiate the performance of the oldest Ss. It thus appeared that the youngest Ss were performing in line with an expectancy theory, but that the performance of the older Ss could be predicted more satisfactorily from a utility theory.

The effects of age and incentive value also were studied by Bisett and Rieber (1966). Prior to introducing the experimental task, the 6- to 7- and 10- to 11-year-old Ss were presented a variety of incentives in paired comparisons to establish what, for each child, was an incentive of high and low value. This procedure had not been followed in the preceding studies, where differences in incentive value were established on the basis of the experimenter's judgment or from preferences children demonstrated in pretests. When the Ss were tested in a two-choice task with only one alternative yielding reinforcement, a higher level of performance was found at both age levels for Ss who were given incentives of high value.

Obviously, factors other than age must play an important role in determining the ef-

fects of incentives on probability learning Weir and Gruen (1965) investigated two other sources of differences, the number of choices and the type of problem The prototypes for the problems were the two-choice problem of Siegel and Andrews (1962) and the three-choice problem The conditions of the Siegel and Andrews study were replicated and extended to include three choices The three-choice problem was presented as it had been in previous studies and modified so that only two choices were available The ratio of reinforcement was 75/25 when there were two choices and 75/125/125 when there were three choices In all cases the Ss were preschool children The results were consistent but perplexing The Ss given a high level of incentive with the Siegel and Andrews two-choice problem performed at a higher level than the Ss given a low level of incentive (prizes versus knowledge of results), thus replicating the earlier results When the Siegel and Andrews task was extended to include three choices, no differences in performance according to level of incentive were found Furthermore, with the standard three-choice problem, Ss performed at a lower level with high incentives than with low incentives, thereby replicating earlier findings with this problem When one of the alternative choices in the standard three-choice problem was eliminated, thus reducing it to a two-choice problem, the differences in performance between the two incentive conditions were minimal

The results of these studies are tantalizing, for although the effects are replicable, the bases of the differences in results remain unknown In general, the study of the effects of incentives on children's learning is a troublesome topic In discrimination learning, differences in performance as a function of level of incentive were difficult to obtain, in probability learning differences were easy to find but hard to understand

Effects of Instructions

It has been suggested in earlier studies and found in the direct verbalizations obtained by Stevenson and Wen (1963) during the course of Ss' performance that children enter the probability learning task with a strong expectation that consistent reinforcement is possible Instructions that there is or is not a

method whereby such a frequency can be obtained therefore should have strong differential effects on performance Wen (1962) investigated this possibility by instructing Ss that there was a way of obtaining a reward on every trial, that there was not a way, or by giving no instructions The Ss were 5- to 7- and 9-year-olds The three-choice problem was used with 50% reinforcement of one response The younger Ss performed at a higher level than the older Ss, but there was no main effect of instructions or an interaction between instructions and age

A subsequent study by Gruen and Weir (1964) included a broader sampling of ages The Ss were 7- to 8- and 12- to 14-year-olds and college students The instructional conditions were the same as those of the previous study, but a penalty condition was added in which Ss were required to return a reinforcer following incorrect response Again, instructions had no overall effect on performance There was an instructions-by-age interaction, where only the college Ss performed in the manner predicted by showing a higher level of response when they were told that no solution was possible The direction of the results was opposite from that predicted for the youngest Ss Overall, level of performance varied directly with age and Ss penalized for incorrect response selected the reinforcing stimulus more frequently than did those who were not penalized Apparently it is very difficult to disengage younger Ss from the sets with which they approach the task by means of verbal instructions

Binary Prediction

Several studies of binary prediction offer additional information about variables that influence trial-to-trial changes in the performance of preschool children A study by Bogartz and Pederson (1966) demonstrates the sensitivity of this type of task Preschool Ss were told they would play a guessing game with lights and the sequence would always be blue-green-blue-green, they were shown how the lights alternated in color In one phase of the study the lights appeared consistently in one window and in the other they alternated between an upper and lower aperture There were more errors and latency of response was greater when the colors remained in the same position than when they

alternated, and more errors generally were made when the intertrial interval was 10 seconds than when it was 3 seconds. The remarkable thing about these results is that differences appeared even after the Ss had been instructed about what would happen.

A second report by Bogartz (1966) presents the results of two other studies with preschool children. In the first, the Ss were given experience, in different orders, with three sequences of events in which the two components appeared as ABAB, ABBABB, or ABBBABBB. When the alternation sequence was presented first, performance improved rapidly, but when it was preceded by experience with either of the other sequences, there was little change in performance. The non-alternating sequences were very difficult for the preschool Ss to learn. In a second study, Ss were given preliminary experience with two events whose probability of recurrence varied so that it was low, at a chance level, or high. When the Ss later were tested with an alternation pattern, Ss who had experienced longer runs of single events showed the least tendency to predict an event opposite to the event that occurred on the preceding trial.

Mathematical Models

Persons interested in mathematical models will be dismayed by the lack of concern in this review with the relation between children's performance and the levels of response predicted from such models. The generation of mathematical models of behavior in situations with uncertain outcomes has occupied a great deal of attention in research with animals and human adults, but with the exception of such studies as those of Atkinson, Sommer, and Serman (1960), Atkinson, Calfee, Sommer, Jeffrey, and Shoemaker (1964), and Bogartz (1965, 1966), few studies have tested such models with children. Since appropriate tests require extended series of trials, and since it is difficult to retain children in testing situations for long periods of time, children may be ineffective Ss for such research. In addition, it is difficult to define a "pure" situation in which a model can be tested and at the same time maintain children's interest in the task. At any rate, it appears likely that the parameters for the equations used in contemporary models will have

to be modified and perhaps extended if they are to encompass developmental changes in performance and the effects of other variables that have been found to influence the behavior of children in probability learning.

CONCEPT LEARNING

Although studies of concept learning have been included in the past several sections, two groups of studies remain to be discussed. Early studies (see Munn, 1954) demonstrated the important roles that age and intelligence play in concept learning. Interest in these variables has persisted, but recent research has been more concerned with investigating the bases for such differences than with uncovering tasks that are sensitive to the effects of these variables.

Developmental Studies

Odom (1966b) has distinguished three levels of learning that may occur in a concept learning task. The most primitive is learning simple S-R relations for the various instances of a concept, an intermediate level involves learning to label the specific instances, and the most advanced level involves learning to label by categories rather than by instances. A situation similar to a reversal shift was devised with pictures of the heads and bodies of animals. During training, the heads of four animals and the bodies of four others were presented in pairs, with reinforcement following choices of heads. (Each category was reinforced for half of the Ss, but for simplicity only one of the sequences will be described.) The portion of the animal not presented during training was used in the transfer trials. The category relevant during training continued to be relevant for half of the Ss, and the other category became relevant for the remaining Ss. Thus in the first case "heads" remained relevant but was represented by new instances, and in the second case "bodies" became relevant—but, importantly, the bodies were those of the animals whose heads had been correct in the training period. The Ss were 5-, 11-, and 14-year-olds.

During original learning, the youngest Ss required four times as many trials to reach criterion as the oldest Ss. When the transfer trials required reversal of the original discrimination, the youngest Ss learned as rapidly as

the oldest Ss. For example, they had little difficulty in learning that the body of the tiger was now correct after having learned that the head of the tiger was correct. The ease with which the youngest Ss learned the reversal apparently indicated that they were not responding at a primitive S-R level but had labeled the stimuli during the training trials and were using the labels to direct their performance in the transfer trials. When, however, the transfer trials required the Ss to continue to respond by category rather than by instance, the 5-year-olds made many more errors than the older Ss, who again learned very rapidly. It was concluded that even though the 5-year-olds had responded mediationaly, they did not use mediational abilities to organize the stimuli by conceptual categories.

Osler and Kofsky have attempted to determine the effects of adding irrelevant information in a concept learning task at different ages. Their first study (Osler and Kofsky, 1965) established that the difficulty of a concept learning task could be increased by adding one or two irrelevant dimensions to the discriminative stimuli in a two-choice task. However, the performance of 4-, 6-, and 8-year-olds did not produce a significant interaction between age and number of irrelevant dimensions. A second study (Osler and Kofsky, 1966) explored the hypothesis that the structure of the task, as well as the presence of irrelevant information, may be an important variable in rate of learning concepts, and that its effects differ, depending upon the age of S. They assumed that younger Ss employ rote learning in a concept learning task, whereas older Ss respond on the basis of categories. The younger Ss therefore should be more strongly influenced by the number of S-R relations present in the task, and older Ss should be more strongly influenced by the number of categories or dimensions on which the stimuli vary. Five-, 8-, and 11-year-olds were tested with one of three sets of stimuli. In one set there were one relevant and three irrelevant dimensions, each represented by two values, in the second set, one relevant dimension represented by two values and one irrelevant dimension represented by eight values, and in the third set, one relevant and one irrelevant dimension, each represented by two values. Thus there were 16 different stimuli in the first two sets and four in the third. The

dimensions of the stimuli differed according to form, color, size, and number. If the preceding reasoning is correct, the younger Ss should perform similarly with the first two sets, but older Ss should find the second set as easy as the third. The results supported these considerations. Five-year-olds made large and equivalent numbers of errors on the first two sets, but with the third set they learned nearly as rapidly as the older Ss. The older Ss learned the second and third sets with equal ease, but the 8-year-olds, and to some degree the 11-year-olds, found the first set quite difficult. Thus the crucial factor for the youngest Ss was size of set, and for older Ss, number of independent dimensions represented in the set.

In a subsequent study, Kofsky and Osler (1967) found the presence of irrelevant information may thwart successful performance by 5-year-olds because of their difficulty in shifting criteria for categorizing stimuli. Children at ages 5, 8, and 11 years showed preferences in the order with which they categorized stimuli such as those used in the previous study, but their preferences had a restrictive effect only on the ability of the youngest Ss to make additional sortings. In concept learning, then, young Ss may perform well if the initial basis for classifying the stimuli is in accord with their preferences, but if it is not they may make many errors before they discern other bases by which they can categorize the stimuli.

Another important process in concept learning is integration of information. The Kendlers have asked when children are able to integrate segments of behavior that previously have been learned but were not contiguously associated. A task was developed for studying this question. In a series of training trials Ss learned that X leads to Y, A leads to B, and B leads to C, the goal. Concretely, the Ss learned to press a lever or push a button to obtain Y and B (e.g., a marble and a steel ball, respectively), and to drop B in a hole to obtain a prize. Training consisted of two steps: first, learning which responses led to Y and B, and second, learning that B led to C. Kendler and Kendler (1962) found that very few 5-year-olds were capable of giving a direct, inferential solution in this problem. By the third grade, however, 73% of the Ss initially selected the A-B segment in a test trial.

and of these, 67% followed directly with the B-G segment

In a second study (Kendler, Kendler, and Cairick, 1966) an effort was made to see whether performance of the younger Ss could be improved if verbal labels were given to Y and B. It was assumed that the label would provide a common stimulus element for the A-B and B-G segments, which would facilitate solution. Kindergarten Ss who labeled the stimuli performed only slightly more poorly than third-grade Ss. As predicted, kindergarten Ss performed more poorly when they did not use labels, but, unexpectedly, labels interfered with the performance of the older Ss. The last finding is interpretable if it is assumed that the labels arbitrarily given to the stimuli by the experimenter may produce interference if they differ from those the Ss spontaneously apply to the stimuli.

Performance in concept learning tasks does not always improve with increasing age. For example, in a study by Friedman (1965) with children between the ages of 6 and 10, performance dropped at ages 8 to 9 in learning a series of sequential-pattern problems. This decline was attributed to the ineffective operation of mediation at these ages. Presumably, younger Ss could learn a pattern of responses (opening doors of boxes in varying orders) by trial and error and the oldest Ss could apply rules leading to efficient performance. The 8- to 9-year-old was assumed to have progressed beyond the trial-and-error to a mediation stage, but "he has not yet learned to use his new tool efficiently. He is so rigid in the application of this newly developing ability that his predictions (i.e., hypotheses) mask the actual regularity of events, thus he is unable to modify his hypotheses so as to include new information" (p. 4). This interpretation is similar to that offered earlier for the poor performance of Ss at these ages in probability learning.

TeVault, Bailey, Cagan, Dionis, and Figelman (1966) attempted to determine whether the hypothesized changes between 8 and 9 years in ability to mediate could be demonstrated with a different task. Half of the Ss were assigned single responses to classes of stimuli (forms) and for the other half the assignment of responses to stimuli was random. Learning was more efficient in the first condition. There was no significant effect associated

with age or the interaction of age with condition. The results were interpreted as not supporting the hypothesis offered by Friedman in the preceding study. Perhaps the most noteworthy aspect of this study, however, was the significant experimenter effect. The results differed, depending upon which of the five experimenters the Ss had been assigned to. Although experimenter effects have been found in studies in other areas of child psychology and in studies with adults, its operation in a study of this type indicates a potentially important source of variance that is often not considered in studies of children's learning. The possibility of significant experimenter effects complicates the design of research. At the same time, a failure to replicate prior results may be due to differences between or among the experimenters rather than to other, seemingly more basic differences in experimental effects.

A common theme runs through all these studies. The young child is viewed as a relatively rigid rote learner whose performance is determined by the number of relations to be learned and whose spontaneous use of verbal labels is restricted to nominal statements about the stimuli. The older Ss, on the other hand, are seen to be flexible and verbally facile and to use these characteristics in successive attempts to isolate the attributes of the stimuli that are relevant for correct response.

Role of Intelligence

Osler and her associates have investigated the relation between intelligence and concept learning in a series of studies. In the initial study (Osler and Fivel, 1961) the correct response in a two-choice discrimination depended upon S's isolating the concept of bird, animal, or living thing. These classes of stimuli were assumed to represent increasingly more difficult concepts. The Ss were 6-, 10-, and 14-year-old children, half above average (mean IQ of 121) and half of average IQ (mean IQ of 101). The older Ss and the brighter Ss at each age learned the concepts more rapidly, and there were no differences in the rate with which the three concepts were learned. To determine whether the concepts were learned rapidly or gradually, performance on the 10 trials preceding criterion were analyzed for each S. Those whose percentage of correct response fell below the

median were classed as sudden learners, and above the median, as gradual learners. The incidence of sudden learners was a function of IQ, but not of age or concept, leading the writers to infer that the brighter Ss were better able to develop hypotheses than were the average Ss.

If bright children develop hypotheses more readily, stimuli that are likely to elicit a wide variety of irrelevant hypotheses should result in bright Ss' performing more poorly than would be the case if the stimuli permitted a more restricted number of hypotheses. The concept "two" was studied by Osler and Trautman (1961) with samples of Ss of the age and IQ levels used in the first study. The concept was represented either by dots or by pictures of common objects. It was assumed that the large number of irrelevant cues contained in the pictures would facilitate the formation of hypotheses. Correct response required that S select the member in each of a large number of pairs that contained two elements and reject the member that contained one or more than two elements. The main effect of age was significant, and IQ interacted significantly with method of representation. The bright Ss had more difficulty in learning the discrimination when the stimuli were objects than when they were dots, but the average Ss learned each with equal ease.

It should be noted that Wolff (1967) in a replication study found no significant interaction between IQ and method of presentation. Both the bright and average Ss performed more poorly when the stimuli were pictures of common objects. Wolff noted that the number of times "one" had been used as the negative instance by Osler and Trautman differed for the two types of stimuli and argued that this contributed to the differences in results. Additional research will be necessary to clarify this.

It is possible that the superiority of bright children lies in their greater capabilities in defining problems, rather than in their being more effective learners. Under the nonspecific instructions used by Osler and Friv (1961), bright Ss performed at a higher level than average Ss. But could their greater effectiveness be traced to their discerning more readily the problem that was to be solved? To investigate this question, Osler and Weiss

(1962) repeated the earlier study with groups of the same ages and IQs, but added a condition in which the Ss were given the explicit instruction "If you look at the pictures carefully you will see that there is something in the pictures like an idea that will tell you which one to choose to get a marble every time." The earlier results were replicated with nonspecific instructions but differences in the performance of the bright and average Ss disappeared when the instructions explicitly defined what the Ss were to do. As expected, type of instructions facilitated the performance of the average Ss and had no differential effect on the performance of the bright Ss.

In a final study of the series, Osler and Shapiro (1964) tested bright and average Ss with continuous and partial reinforcement. The task involved discriminating between two and three circles appearing in different spatial arrangements. The bright Ss were significantly superior to the average Ss when continuous reinforcement was available. With partial reinforcement, performance did not differ according to the level of IQ. Support thus was obtained for the hypothesis that the performance of bright Ss would be disrupted to a greater degree than would that of the average Ss when their efforts at generating rules met with only partial success.

These studies point to several factors that distinguish the concept learning of bright Ss. Bright Ss appear to be able to define problems more readily and to produce more hypotheses than average children. When the formulation of many hypotheses is of assistance in the development of the correct response and when there is consistent affirmation of the utility of a particular hypothesis, bright Ss perform at a higher level than average Ss. When the stimuli elicit few hypotheses and when the problem is clearly defined, IQ, at the levels tested, is not a critical variable in concept learning.

PAIRED ASSOCIATE LEARNING

The learning of paired-associate lists is among the most venerable of psychological problems. There has been a long history of intensive research with human adults as Ss, but relatively few studies with children were published until recently. Why child psycholo-

gists shied away from this problem for so many years is not clear, especially since learning to associate names and places, dates and events, occupies so much of the child's time in school and, consequently, becomes a problem with practical significance. At any rate, once research with children began to be published, it rapidly became apparent that paired-associate learning was a sensitive means of investigating the effect of many variables that have important implications for a wide variety of learning tasks.

Associative Strength

The effects of the associative strength of the S and R elements have been studied by selecting response elements that differ in their associative strength to the stimulus elements in the child's natural language. Castaneda, Fahel, and Odom (1961) established the free-association value of a list of words for fifth and sixth graders and then constructed paired-associate lists by using strong or weak associates of the stimulus items. Learning was significantly faster when the associative strength was high, a result that would be expected except for the fact that it is difficult to demonstrate this effect with adult Ss. This finding has been replicated by McCulleis (1961) and extended by Wicklund, Palermo, and Jenkins (1964). The availability of more extensive word association norms enabled the latter authors to make a more sensitive test of the effect of associative strength on learning. Lists of 10 items were constructed so that the responses were primary associations to the stimulus words or were of medium or very low strength. In addition, half of the primary responses were high-frequency responses and half were of low frequency. The ease with which fourth-grade Ss learned the lists varied directly with the strength of the associations and the primary responses were learned more rapidly when they were of high frequency.

Klinger and Palermo (1967) found the same general results when the lists were presented aurally to first and fourth graders. The effects differed at the two age levels. Performance was similar at the two ages on a control list in which the S-R relations had no associative strength. But when the lists contained items of either high or low associative strength, the older Ss learned with

great rapidity, whereas the performance of the younger Ss began at a low level and never reached that of the older Ss. The greater linguistic experience of the older Ss apparently enabled them to benefit from lists that contained items with some natural associative S-R relation.

In a study by Shapiro (1965), items with high and low association value were arranged to form a noncompetitive list (the R was paired with the S that elicited it in free association) or a competitive list (the list was rearranged so that the R was paired with an S different from that which elicited it in free association). It was predicted that strongly associated elements arranged in a competitive list would generate a high degree of interference but that when arranged in a noncompetitive list they would produce facilitation. The Ss, fifth graders, were selected from the sample used in establishing the word association norms and their responses had either high or low degrees of commonality with the responses most frequently made by the Ss in the normative group. This variable was introduced to determine whether group norms would be a more effective basis for prediction when the responses of the individual S were in close concordance with these norms than when they were not. Learning was more rapid with high-association pairs, noncompetitive pairings, and for Ss with high commonality scores. Better performance for high-association pairs was found on the noncompetitive lists, but there was no difference in the competitive lists according to strength of S-R association.

A study of Palermo, Flamer, and Jenkins (1964) found similar effects when the association value of the response elements was varied by using consonant-vowel-consonant nonsense syllables with association values of 20, 50, and 80%. Adjectives served as the stimulus elements. The difference in rate of learning the extreme lists was significant for the fifth-grade Ss. Further, when the response elements were numbers that were presumably highly meaningful, the Ss learned the associations more rapidly than when they were nonsense syllables with low association values.

The facilitating effect of using items with high associative strength extends to studies where the response element is omitted on a portion of the trials (Carroll and Penney,

1966) The learning of items with low associative strength was more strongly disturbed by the partial omission of the response element than was the learning of items with high associative strength

A different approach has been used by Ramirez and Castaneda (1967). They selected names of children who had received either high or low sociometric ranks for use as the stimulus elements. More behaviors were assumed to be associated with the names of children with high sociometric rank, thus making their names more meaningful. The rate of learning to associate consonants with names was faster when the names were of children with high sociometric ranks. That the effect was not due to some other factor, such as general association value of the names or pronounceability, was seen in the fact that children unfamiliar with the names learned the two lists in equal numbers of trials.

Another related study is that of Parvilo and Yuille (1966), who found more efficient learning when the materials were high-frequency, concrete nouns than when they were high-frequency, abstract nouns. The effect was more pronounced when the nouns functioned as stimulus elements than when they were the response elements. The basis of the effect is not clear, but concrete nouns may elicit a greater number of facilitating associations than do abstract nouns.

Mode of Presentation

Since much of the formal learning of the young child occurs through the auditory mode, learning of paired associates might be more rapid if the items were presented by the aural than by the traditional visual mode. Shapiro (1966) tested this possibility with 10-, and 11-, and 13- and 14-year-olds. Lists contained items with high or low interresponse competition and high or low associative strengths. Learning was faster with the noncompetitive lists, and items of high associative strength in noncompetitive lists were learned more rapidly than were items of low associative strength. The main effects of age and mode of presentation were not significant, nor were the interactions of these variables with either of the other variables. However, when the analyses were made separately at each age, it was found that the younger Ss but not the older Ss learned faster

with aural than with visual presentation. More rapid learning with aural than visual presentation also was obtained by Budoff and Quinlan (1964) in a study with 7- and 8-year-olds. When, however, the visual stimuli are pictures rather than words, no differences were found between modes in the rate of learning by 7- and 8-year-olds (Hill and Hecker, 1966).

These results suggest that young children may have difficulty with visually presented material because of their lack of experience with written words. Levin, Watson, and Feldman (1964) therefore assumed that pretraining young children on the construction of words might facilitate later learning. Since an earlier study had indicated that the number of confusions in verbal learning was greatest when two or more words shared an initial grapheme and was least when they shared medial graphemes, first-grade Ss were trained on initial, medial, or terminal graphemes of an artificial orthography devised for use in an eight-item paired-associate task. The Ss were required to trace the graphemes occupying one of the positions in each of the artificial words three times. Overall, none of the groups performed differently from a control group, which did not have the tracing experience, but the number of correct responses in the paired-associate task was in the predicted order, and the number of correct responses of the group tracing the initial graphemes was significantly higher than that of the group tracing the medial graphemes.

The most extensive investigation of this topic has been reported by Otto (1961), who selected Ss at grades 2, 4, and 6, who were good, average, and poor readers, and who had IQs between 95 and 110. The task involved learning to associate low association value nonsense syllables with geometric forms. Three modes of presentation were used: (1) visual, (2) visual presentation of the form, reading of the nonsense syllable by the experimenter, and (3) a combination of the first two, plus the requirement that S trace the nonsense syllable with his finger. The poor readers in grade 2 required approximately twice as long to learn the list as the good readers, but by grade 6 the difference had decreased. There was no interaction between reading level and mode of presentation, as might be expected, but mode of

presentation did interact significantly with grade. The combined mode of presentation (3) was most effective for the grade-2 Ss, the visual mode was most effective at grade 4, and at grade 6 the two modes were of approximately equal effectiveness. Verbalization of the response element produced the slowest learning at the two higher grades but was somewhat better than the visual mode at grade 2.

Several other studies deal with quite different questions related to the effects of different modes of presenting paired-associate materials. The learning of paired-associate lists often is discussed as involving two steps: first, delimiting the alternative responses, and second, attaching the responses to the stimulus elements. If this description is correct, learning should be faster if all response elements are presented to Ss on each trial than if, as is the usual case, they become known only during the course of successive trials. Carroll (1966) found the 10- and 11-year-olds did learn more rapidly in the former than in the latter case. It also is possible that learning would be faster if the lists were presented in a constant rather than a varied order. Samuels and Jeffrey (1966) found that the number of correct responses was higher with a constant order when the response items were of high similarity, but order was not a significant variable when the responses were of low similarity. Finally, learning of individual items may be more rapid if only a small number of items are presented. In a large parametric investigation, including lists of 4, 8, 12, and 20 items, Carroll and Buike (1965) found with tenth graders, however, that "items appear to be acquired one by one and at a rate that is relatively independent of the total number of items presented in a given trial or session. For example, it has been shown in this study that it takes about the same amount of exposure and response time for an S to acquire 4 items regardless of whether they stand alone or are embedded in a list of 20 items" (p. 552).

Affective Factors

The role of affective factors, such as anxiety, stress, and conflict, has been studied extensively in the paired-associate learning of adults. There are fewer studies with children,

but the results obtained with children and adults are similar. Most of these studies have sought to evaluate the hypotheses that (1) strength of response is a function of the product of level of drive and habit strength and (2) general level of drive is increased by the presence of affective factors such as those previously listed. According to these hypotheses, high drive should result in improved performance when habit strength of the correct response is high. When, however, the habit strength of the correct response is lower than that of alternative, competing responses, high drive should disrupt performance.

A study by Lipsitt and Spears (1965) illustrates how these predictions have been tested in paired-associate learning. Triads of stimuli were constructed so that one response was strongly associated with all three stimulus elements, but for two of the pairs, the correct response was a weak associate. For example, if the triad was fork-eat, knife-hat, spoon-door, the tendency to respond "eat" to each of the stimuli, should be strong for all Ss, but of greatest strength for the Ss with high drive. Two studies with sixth-grade Ss were reported. In one, drive level was manipulated by selecting Ss from extreme scores on a paper-and-pencil test of manifest anxiety, and in the second, an effort was made to increase drive for half of the Ss by giving instructions that emphasized the importance of responding correctly and doing as well as other children. The results partially confirmed the hypothesis. Performance on the low-association items was impaired for high-anxious and stress-instructed Ss, but no differences occurred for the high-association items, partly because they were learned with great ease. The mechanism assumed to account for differences in performance was not relevant, for the errors were mostly extralist errors and neither anxiety nor stress increased the tendency of Ss to make the high-association response, as was predicted.

More generally supportive evidence for the hypothesized mechanism was found by Castaneda (1961) in a motor paired-associate task with fifth graders as Ss. Five lights appeared in a horizontal array, and below each light was a response button. The Ss were assumed to have a strong tendency to press the button directly below each light. For some light-button combinations these ten-

dencies resulted in correct response, but for other combinations correct response required the Ss to make a nondominant response. High levels of anxiety were predicted to result in better performance when the dominant response was correct (i.e., habit strength was high) but poorer performance when the dominant response was incorrect. In the second case, the heightened tendency to make the dominant, incorrect response would result in more errors. The results revealed a significant interaction between level of anxiety and type of button correct, with each of the differences being in the predicted direction. There were more dominant response errors for the high- than for the low-anxious Ss and the number of random errors made by the two groups did not differ. Similar results were found in the same type of task by Castaneda and Lipsitt (1959) when drive level was manipulated by introducing stress in the form of a time pressure for response. Impaired paired-associate learning with high levels of anxiety has been reported in several other studies. Stevenson and Odom (1965) obtained significant negative correlations between rate of learning and anxiety scores for boys at grades 4 and 6. The correlations for girls were negative but were not significant. Castaneda, Palermo, and McCandless (1956) presented high- and low-anxious Ss with a five-light-five-button motor paired-associate task. Performance of the two groups was compared for the two easiest and two most difficult combinations. Compared to the low-anxious Ss, high-anxious Ss performed better on the easy combinations and more poorly on the difficult combinations. These results are in line with the assumption that level of difficulty of the combinations was determined by the number of competing responses, all of which would be of higher strength for the high-anxious Ss. Poorer performance of high-anxious Ss also was found in a four-light-two-button task (Palermo, Castaneda, and McCandless, 1956). Here it was assumed that only two alternatives for response would increase the likelihood that competing responses would be present, thereby making this a relatively difficult task.

A within-Ss design has been used in several studies of this general problem. The proposition tested in these studies was that "conditions which produce associative interference,

that is, competition between incompatible response tendencies, may serve to engender motivational states in the S" (Castaneda, 1965, p. 2). To test this proposition, paired-associate lists were constructed in sets of two so that the presence of competing associations was maximized for some of the sets but minimized for others. Test pairs were interspersed among these two types of set, always following a set of items with high or low competing associations. Half of the test pairs were strong associates and half were weak, but neither had a strong associative relation with the other items. The measure of central interest was the number of trials to reach a criterion of one errorless trial on the test pairs. It was assumed that the competing associations would generate states of conflict that would result in an increased drive level, which, in turn, would facilitate performance for test pairs where the associative connections were strong and interfere with performance for test pairs where the associative connections were weak. A significant interaction was obtained between type of training pair and type of test pair. The predicted facilitating effect of conflict on the learning of the test pairs with strong associative connections was obtained, but the difference for the weakly associated test pairs was not reliable. A variant of this procedure was employed by McCullers (1967), and again performance for strongly associated test pairs improved as interference within a training pair increased but no effect was found for the weakly associated test pairs.

Mediation

The paired-associate task is a convenient, frequently used method for investigating the effects of verbal mediation on learning. Some studies with children have used the classical mediation paradigms developed in research with adults. In these paradigms, potential mediators are developed during the course of the experiment or are derived from associations occurring in natural language. For example, potential mediators may be developed during the course of a study by requiring Ss to learn three lists of pairs of words: first, they learn to associate A with B, then B with C, and, finally, A with C. Word B is assumed to function as a potential mediator which, if effective, would facilitate the learning of the association A-C. By appropriate arrangements, the me-

diator may be used as a potential source of interference in learning the A-C association. It is possible to eliminate the first of the three stages by selecting words for the A-B associations from high-frequency associates in word-association norms. Other techniques for providing potential mediators between the stimulus and response elements have involved linking the two elements by verbal and pictorial means, and by varying the syntactical relations embodied in the mediating words and pictures.

Noircross and Spiker (1958) were able to demonstrate both facilitation and interference in the paired-associate learning of 5- and 6-year-olds with the three-stage paradigm. Facilitation was produced by pairings such as those described in the preceding example, interference was produced by arranging the pairings in the third list so that the potential mediator would elicit incorrect responses and thereby interfere with learning. Wismer and Lipsitt (1964) obtained similar effects with fifth graders, although the interference effects were much more pronounced than were the facilitation effects.

The same types of effects have been found when conditions are arranged so that the presumed mediation occurs during the learning of the A-C list (Palermo, 1962). In this design, only A-B and A-C lists were presented and in each list there were six stimulus elements and three response elements. After the A-B list was learned, new responses were paired with the old stimuli in a manner that would be expected to produce facilitation, interference, or no effect. Using the facilitation arrangement as an example, the response "scissors" was paired with both "stool" and "shoe" in the first list. In the second list, both stimulus words were associated with the response "house." Since both stimulus elements were associated with the same response element in each stage, the strengthening of each association in the second stage should facilitate the learning of the other because of the tendency for each to elicit the common mediator "scissors."

Nikkel and Palermo (1965) used both A-B, B-C, A-C, and A-B, C-A, C-B paradigms in a study with sixth graders, where the words entering the A-B association were selected because of their high association value. Here, as in all of the studies, a control group, in

which the associations developed in the second stage were irrelevant for learning in the third stage, provided the basis for determining the presence of facilitation or interference. The results were similar for the two paradigms, the fastest learning of the A-C and C-B lists occurred in the facilitation conditions, and the slowest in the interference conditions. Thus existing language habits significantly influenced the acquisition of new verbal habits, apparently by implementing the mediation process. Palermo (1966) extended the findings with sixth graders to lists of the forms C-B, B-A, A-C and B-C, B-A, A-C. The relative differences among the facilitation, control, and interference conditions were as great in this study, where one or two backward associations were necessary for mediation to occur, as they were in the other studies, where only forward associations were involved.

A different approach was used by Reese (1965) in an investigation of the roles of verbal and visual content of the response items in paired-associate learning. The Ss were preschool children at three age levels (average ages 44, 58, and 77 months). The stimuli were pictures of animals and the responses were either pictures of objects or drawings of the animals engaged in activities with the objects (e.g., cat carrying an umbrella). On the first trial, the experimenter either verbalized the response or described the interaction between the animals and the objects. The group that saw and heard only the response was inferior in learning to the other groups, whose scores were approximately equal. The main effect of age was significant, but age did not interact with content of the response. Thus learning to associate two words was facilitated when the experimental conditions supplied a connective link, either verbal or visual, between the stimulus and response elements.

Numerous other studies have found that paired-associate learning is facilitated if the stimulus and response elements are connected by verbal or pictorial means. Davidson (1964) divided sixth graders into five groups, each trained under a different mediation condition. The stimuli were pictures of common objects. The conditions included (1) presentation of the pictures, (2) the experimenter named the pictures, (3) the experimenter named the pictures and provided a connecting preposition,

(4) the experimenter used the objects in the context of a descriptive sentence, and (5) the sentence of the preceding condition was read and a picture was presented that depicted the relation described in the sentence. The different treatments were applied only on trial 1. Learning was significantly slower in the first two than in the last three conditions, indicating that when a connective relation between the stimulus and response elements was present, even in the form of a preposition, learning was facilitated.

Syntactical mediation as a function of age has been studied by Jensen and Rohwer (1965) with children at six age levels between 5 and 17 years. On the initial trial, half of the Ss were asked to construct a sentence relating the stimulus and response elements (common objects) and half were not. A dramatic effect was obtained when Ss were asked to construct sentences. There were no age differences in rate of learning after age 7. When Ss were not required to construct sentences, age differences continued to be found. Even the performance of the oldest Ss was influenced by being asked to construct a sentence, apparently because this induced them to mediate earlier than otherwise would have been the case.

Providing verbal links between the stimulus and response elements obviously facilitates learning, but would similar facilitation occur if the links were presented pictorially? Rohwer, Lynch, Suzuki, and Levin (1967) extended Reese's (1965) study to include three verbal connectives—conjunctions, prepositions, and verbs—and three parallel pictorial connectives—coincidental, locational, and actional. Among the verbal connectives, only a connective verb produced more rapid learning than occurred in a control group where the objects merely were named. Among the pictorial connectives, more rapid learning occurred with actional (all materials were presented by means of movies) than with locational and with locational than with coincidental pictorialization. The order of the facilitative effects obtained with the verbal and pictorial connectives was approximately the same and equivalent effects were found for Ss at grades 1, 3, and 6.

A companion study (Rohwer, Lynch, Levin, and Suzuki, 1967) contrasted the rate of learning when the objects were presented

pictorially and when printed names of the objects were used. Learning was more rapid at both grades 3 and 6 with pictorial than with printed materials, and, confirming the earlier results, learning was more efficient when the experimenter related the stimulus and response elements by a verb than when they were related by a preposition or a conjunction. Other studies (Rohwer, 1966, Rohwer and Lynch, 1967) add further evidence of the greater facilitating effects of verbs than of conjunctions or prepositions as connective links, but the basis of the facilitation by verbs remains unclear. It does not seem to be due solely to the fact that verbs exercise greater constraints on the number of possible words that can follow them than do prepositions or conjunctions, but alternative explanatory mechanisms have not been established.

Although the study by Martin and Jones (1965) of grammatical units in paired-associate learning does not deal with mediational processes, it is of relevance in the present discussion. Fifth and sixth graders were presented single-word nouns or noun phrases as stimulus elements and single-word verbs or verb phrases as response elements. The two words within each phrase either conformed to common grammatical order or the order was reversed (e.g., an apple versus apple an, woke up versus up woke). As measured by rate of learning, single-word nouns and noun phrases were functionally equivalent, except when the two words of the noun phrase were in the reverse grammatical order, but the Ss learned pairs involving single-word verbs more rapidly than verb phrases and these, in turn, more rapidly than pairs involving verb phrases in reversed grammatical order. Hence there was a significant influence of daily language habits on the ease of paired-associate learning.

The findings of these studies are remarkably consistent. Learning to associate words occurs more rapidly when a third word is available as a mediator or when a connective link between the words is established by verbal or pictorial means. Within the ages studied, the effects were of similar magnitude and age consistently failed to interact with experimental conditions. It appears that by the time children enter school the mediational processes occur in the same manner, although more slowly than they do at later ages.

Transfer

If a response is associated with a particular stimulus in an initial task and in a subsequent task a new response must be associated with the stimulus, the amount of training received on the first task should result in increasing interference in learning the new association. Spiker (1960) reported three studies aimed at determining (1) the relation between amount of initial practice and degree of interference and (2) whether similar results would be obtained if the effects of initial training were heightened by instructing Ss to rehearse or to use mnemonic devices (e.g., imagine a boat made of cake). Sixth graders received either 6 or 15 trials in learning four paired-associates. They were then presented a new list of eight items in which the stimuli of four of the original pairs were coupled with new responses, along with four new S-R pairs. The difference in rate of learning the two types of item was greater for the group that received the greater number of trials, apparently reflecting greater interference for these Ss in learning new responses to the old stimuli. At the same time, the extended training resulted in superior performance in learning the new S-R pairs, demonstrating a nonassociative form of facilitation. The same effects were produced by rehearsal and use of mnemonics.

Spiker and Holton (1958) found similar results when groups were given 5, 10, or 20 trials on the initial task: the more training given on task 1, the greater the interference on learning in task 2. The interference effect appeared to be attributable in part to the fact that Ss failed to respond within the time limit allowed (2 seconds). It seemed likely therefore that extending the amount of time for response would reduce the interference effect. This suggestion was tested by White, Spiker, and Holton (1960), who repeated the earlier study with a 4-second interval for response. Degree of training on task 1 now failed to produce differences in associative interference as measured by frequency of correct response. When speed of response was considered, some evidence of greater interference for a 20-trial group than for a 5-trial group was found. Extending the time interval for response also produced improved performance by preschool Ss (Price, 1963). These Ss performed more poorly with a 2-second than with a 6-second

anticipation interval, but when, during the later stages of training, the interval was 6 seconds for all Ss, roughly equivalent levels of performance were attained. Since the level of performance of the 2-second group improved rapidly with the longer interval, shorter time intervals appeared to affect performance rather than learning.

A transfer design was used by Rice and DiVesta (1965) to test semantic and phonetic generalization in paired-associate learning. Third, fifth, and seventh graders initially learned nonsense syllable responses to a set of three training words. A second list of 12 items was constructed by substituting as stimulus elements a homonym, antonym, synonym, or a control word for each training word. No differential transfer was found for third graders in learning the second list; rate of learning to associate the nonsense syllables did not differ for the four categories of test stimuli. At grades 5 and 7, however, more correct responses were found for homonyms, antonyms, and synonyms than for the control words.

INCIDENTAL LEARNING

Until now, the problems have involved intentional learning where Ss were given explicit instructions about what they were to do and the cues provided a relevant basis for correct response. But does learning also occur when the Ss are not instructed to learn or when the cues contain information that is irrelevant for correct response? Casual observation indicates that learning does occur under such conditions, and the results of experimental studies have substantiated such observations. Depending upon such factors as the age of the child and the experimental conditions, however, the degree of incidental learning does differ.

Developmental Differences

One of the first developmental studies was reported by Stevenson (1954), who tested children between the ages of 3 and 7 years. At each end of a life-sized Y-maze were two boxes, one locked with a padlock. The S was told to go to the open box, find a key, and open the locked box to find a prize. In each open box was an assortment of objects, including on one side a small white purse, and

on the other side a matchbox. Depending on the experimental condition, the key was on, under, or in the purse and matchbox. After an equal number of experiences with each side of the maze, the S was asked to find the purse or the matchbox. Since neither object had been mentioned by the experimenter and since there had been no necessity for Ss to learn their location, the ability of Ss to locate the object was assumed to be the result of incidental learning. The frequency of correct response increased significantly with increasing age and differed significantly among the experimental conditions. The greatest frequency of incidental learning occurred when the incidental object had to be manipulated (key in the object) and the least when no manipulation was necessary (key on the object).

Would the tendency to acquire irrelevant information continue to increase if still older Ss were tested? It can be argued that it would not. If the mature organism were responsive to the vast array of incidental stimuli that is continually available, he would be so flooded with momentarily useless information that appropriate response would be disturbed. To maintain behavior in an efficient and effective manner, the organism eventually must become selective in his attention, responding to relevant stimuli that have no immediate utility.

Maccoby and Hagen (1965) provided data relevant to this discussion in a developmental study of incidental recall in first, third, fifth, and seventh graders. It was assumed that the young child is handicapped in focusing his attention selectively because of his inexperience in discriminating between task-relevant and task-irrelevant aspects of a stimulus complex. As the child learns to categorize, code, and label objects, incidental learning may increase, but at a later stage selective attention becomes possible. Consequently, it was predicted that the relation between age and incidental learning would be curvilinear. A set of cards bearing different colors and different pictures was shown to the child. The cards were then turned over and the child was asked to point to the card bearing a particular color. Incidental recall was tested by asking the child to find cards bearing particular pictures. There was a very modest increase in number of correct responses between grades 1 and 5, and a significant decrease between grades 5

and 7. The correlations between performance on the intentional and incidental tasks were nonsignificant, indicating that the acquisitions of the central and incidental information were not reciprocal processes.

A curvilinear relation between incidental learning and chronological age also was found by Siegel and Stevenson (1966) with a different type of task. The Ss were between the ages of 7 and 14 years, roughly the ages of the Ss in the previous study. A standard three-choice successive discrimination problem was followed by the presentation of each of the discriminative stimuli imbedded in a stimulus complex. In this second phase, which constituted an overlearning period for the original discrimination, each stimulus complex was presented 12 times. To test incidental learning, the incidental objects then were presented separately. The question was whether the Ss would make the response to the incidental object that had been correct for the discriminative stimulus with which it had been associated. The frequency of correct response increased significantly between ages 7 to 8 and 11 to 12 and decreased significantly between ages 11 to 12 and 13 to 14. Again, there was no significant correlation between the measures of incidental and intentional learning.

A closely related study by Ciane and Ross (1967) assessed the ability of 8- and 11-year-olds to profit by the presentation of information that was irrelevant to their performance at one stage, but later became relevant. A two-choice discrimination problem with either form or color as the relevant dimension was presented during an original learning period. The irrelevant cues appeared on every trial but in a varied manner, so that each cue was associated with reward on only half of the trials. If form was the relevant dimension, color was irrelevant, and vice versa. When Ss reached criterion on this problem, the irrelevant cues were made 100% redundant for the experimental groups. The original procedure was continued for the control groups. In the third stage, the irrelevant cues became relevant, the cue that had been associated consistently with reward was correct for half of the experimental Ss and the cue that had been paired with the nonreward was correct for the other half. The different conditions of the third stage resulted in different rates of learn-

ing by the younger, but not by the older Ss. The younger Ss learned the problem when the previously "positive" irrelevant cue was correct more rapidly than when the previously "negative" irrelevant cue was correct or than in the control condition. Thus the redundant cues of the overtraining phase had acquired functional significance for the younger Ss, but the older Ss appeared to have concentrated their attention more completely on the relevant aspects of the stimuli.

Other Studies

A study by Hetherington and Banta (1962) provides additional information about the relation between incidental and intentional learning. Six-year-olds were given a color-naming test in which cards of different colors also contained different pictures of common objects. After a delay of 2 days the Ss were asked to recall the names of the objects. The procedure was repeated, but now the Ss named the objects and were instructed to try to remember their names. As found in the previous studies, there was no significant relation between the intentional and incidental learning scores. What causes an S to demonstrate a high degree of incidental learning is not clear, but whatever the bases, they apparently are not the same as those producing a high degree of intentional learning.

Some studies with adults have found that increased motivation results in poorer incidental learning. The effect has been attributed to the restriction of perceptual range with heightened motivation. Kausler, Laughlin, and Trapp (1963) tested seventh and eighth graders to determine whether a similar effect would be found with children. A 14-item serial learning test involving seven forms was presented to the Ss. Each form appeared with two of seven colors. Incidental learning was measured by the number of correct form-color pairings the Ss could recognize when all combinations were presented on a printed sheet. Half of the Ss were told at the beginning of the study that they could win money as a prize, and half simply were asked for their cooperation. Incidental learning was greater when Ss were offered money, both for Ss who later stated they had tried to learn the color-form combinations and for Ss who stated they did not. Perhaps the type of drive as well as the strength of drive is important in determining

the incidence of incidental learning. In this study a nonaversive drive was used, whereas the studies with adults involved aversive drive states such as hunger or anxiety.

INTERRELATIONS IN LEARNING

In the preceding section it was seen that incidental and intentional learning apparently involve different psychological processes, for scores obtained on tests of the two types of learning were not significantly correlated. This opens an interesting topic, that of ascertaining the interrelations among various tasks that are used to measure children's learning. Thus far, there has been no discussion of the correlations among scores obtained in different types of learning tasks. There is a very simple reason for this. The common practice has been for an investigator to use a particular type of problem to assess the influence of certain experimental variables, and rarely have the same Ss been presented more than one type of problem. Data are available, however, concerning the intercorrelations among scores obtained on a variety of learning tasks. These studies have tended to be undertaken by persons interested in the analysis of the psychometric structure of learning ability and have been concerned with the question of whether learning is a unitary function or whether it is necessary to posit different types of learning abilities.

One of the earliest studies with children was Husband's (1941) investigation of the effects of the range of intelligence on the interrelations among tasks. It had been suggested that the low correlations typically found among learning tasks with adults resulted from the restricted ranges of intelligence sampled in the studies. Husband presented a series of tasks to Ss in grades 7 and 8 with IQs ranging between 81 and 162. The median correlation among tasks was .10 and the range of correlation was similar to that found in the earlier studies. Although the median intertask correlation was low, high correlations sometimes were found between similar tasks, such as rate of learning a finger maze and a mental maze ($r = .37$).

A more extensive study was reported by Stake (1961), who presented 12 learning tasks to 240 Ss in grade 7. The tasks differed on three dimensions, content (verbal-nonver-

bal), type (rote, relational), and mode of presentation (group versus gamelike individual tests). Each S's performance on each task was fitted to a theoretical learning curve with three parameters. The highest intercorrelations were obtained with the parameter of asymptotic level as measured by total errors. The medians of the correlations between asymptotic level for each task and all other tasks varied between .10 and .30. The highest correlations were those between two forms of the same learning or memory task or between various memory and learning tasks. Stake concluded that his results provided no evidence for a general learning factor, for the separation of rote and relational learning, or for verbal tasks to load on a verbal learning factor. Further, mode of presenting the material had no differential effect on the correlations, individual differences in performance were comparable for Ss tested in groups and individually.

A study by Duncanson (1964) included three types of task: rote memory, paired associates, and concept formation. Three types of material were used in each task: verbal, numerical, and figural. The tasks were given to 102 Ss in grade 6. Duncanson obtained a set of coefficients for each S on the basis of the number of components necessary to describe his performance. The intertask correlation matrix yielded correlations of approximately the same magnitude as those found in previous studies. A number of significant correlations were found between the various rote memory and paired-associate tasks, but there were few instances of significant relations between either concept formation and rote memory or concept formation and paired associates. A factor analysis of the data yielded more distinct separations of the tasks than had been found by Stake. Tasks involving words had high loadings on verbal factors and tasks involving numbers and figures had high loadings on nonverbal factors. The most unexpected result was the specificity of the concept-formation factor, which was defined solely by the three concept-formation tasks.

Stevenson and Odom (1965) reported the interrelations among performance in five tasks: paired associates, two discrimination learning tasks, a concept-formation task, and anagrams. The Ss were 354 children enrolled in grades 4 and 6. The median correlation among the

tasks was .17. There were no significant correlations between the two most complex tasks, concept formation and anagrams, but the correlations between what had been presumed to be the most simple and the most complex tasks, paired associates and anagrams, were consistently significant across both grade and sex. Consistently significant correlations also were found between the two forms of discrimination learning.

The previous study was extended by Stevenson, Hale, Klein, and Miller (1968) to include 12 different tasks, consisting of paired associates, discrimination learning, probability learning, incidental learning, and tasks involving verbal memory, concept of probability, concept of conservation, and anagrams. The Ss were over 600 children in grades 3 to 7. In analyses of the data obtained over a broad range of intelligence at grade 7, the median intercorrelation among tasks was .30, when the analyses included samples of Ss of average ranges of IQs across all grades, the median intercorrelation was .20. The correlations were somewhat higher than those found in the previous studies, but even here fewer than 10% of the correlations were above .50. Tasks that were highly similar in structure, such as the two paired-associate, the two memory, or the two concept of probability tasks, tended to be significantly related in all analyses. The presence of verbal material in a task appeared to be the single most important determinant of the frequency and magnitude of the correlations found in the study. The greatest number of significant correlations was produced by paired associates, verbal memory, and anagrams, all of which were highly dependent upon verbal processes. The frequency of significant correlations among the learning tasks was no greater than that among the remaining tasks, which were assumed to be examples of problem-solving tasks.

The number of studies is small, but the results are consistent. Low positive intercorrelations tend to be found among different learning tasks, except when the tasks are similar in structure, or, in some cases, similar in content. These results are comparable to those found in studies with human adults and animals, even though the studies with children have tended to include larger and more heterogeneous samples of Ss. Thus far, at

least, there appears to be little basis for assuming that learning represents a unitary function that operates in a similar manner across different learning tasks. Information is too limited to draw more than this negative conclusion, which, in itself, is absorbing information for anyone who is tempted to construct a theory of learning based on children's performance in a restricted sample of problems.

✓ LEARNING AND INTELLIGENCE

Intelligence often is assumed to be closely related to the child's ability to learn and results of intelligence tests frequently are used to make predictions about future academic success. In fact, Binet's original work on the construction of intelligence tests was instigated by the request of city authorities to develop an instrument to identify slow learners before they entered the Paris public school system. Although there have been many studies of the relation of IQ to performance in school, there have been remarkably few studies of the relation of IQ to performance in standard learning tasks.

The early studies of sensorimotor learning reviewed by Munn (1954) generally revealed little, if any, correlation between children's rate of learning and IQ, and low correlations were reported for more complex serial learning tasks by Garrett (1928) and Garrison (1928). These studies were criticized, however, because of the restricted range of ability represented in the groups from which the Ss had been drawn. Husband (1941) attempted to counter this criticism by sampling from a broader range of intelligence, but the magnitudes of the correlations were similar to those that had been found in other studies. Some correlations, however, were moderately high, for example, the correlation between rate of learning a finger maze and IQ was .38 and between rate of learning a mental maze and IQ was .34. Similar results were found by Simrall (1947), who used gam scores of seventh graders derived from the repeated administration of the Thurstone Memory, Spatial Relations, and Perceptual tests. The gam scores were not highly correlated with IQ or with each other. On the basis of her study and previous studies, Simrall concluded that

intelligence could not be defined as the ability to learn.

The results of four recent studies do not lead to quite so negative a view. In the studies by Stake (1961), Duncanson (1964), Stevenson and Odom (1965), and Stevenson, Hale, Klein, and Miller (1968), high frequencies of significant correlations between performance on learning tasks and IQ were found. The median correlation between Otis IQ and error scores was .36 in the study by Stake. The tasks for which the correlations were above the median included various forms of paired-associate learning, memory for patterns of numbers, and verbal memory. Duncanson found a median correlation of .24 between Kuhlmann-Anderson IQ and the coefficient for the first component in his analysis of the learning curves obtained from three forms of paired-associate learning, concept formation, and rote learning. The highest correlations ($r = .43$ to $.44$) were between IQ and verbal paired-associate learning, verbal rote memory, and figural rote memory. In the study by Stevenson and Odom, correlations for paired-associate learning and anagrams with Lorge-Thorndike IQ ranged between .28 and .57. The concept-formation tasks used in all three studies yielded a median correlation of .11, with no correlations with IQ above .29. In the study by Stevenson, Hale, Klein, and Miller a median correlation of .34 was found between Lorge-Thorndike IQ and performance on 12 learning and problem-solving tasks when the analyses included seventh-grade Ss representing a broad range of intelligence, and a median correlation of .37 when the analyses included children in grades 3 to 7 with an average range of intelligence. Particularly high frequencies of significant correlations were found for tasks with verbal content: paired associates, verbal memory, and anagrams.

Another group of studies relating IQ and performance in learning tasks has been reviewed by Zeaman and House (1967). Although these were not correlational studies, level of intelligence was related to learning by comparing the performance of groups of Ss differing in IQ or MA. Comparisons of groups differing in IQ yielded fewer differences in performance than comparisons of groups differing in MA. Differences specifically associated with IQ appeared only when

the groups differed greatly in intellectual level or when the tasks were very complex

The results of these studies lead to the conclusion that although level of intelligence may be a significant determinant of performance in learning tasks, intelligence and learning ability are not identical functions. Those instances in which moderately high correlations have been found tended to use verbal material, tests of the ability to acquire associations, and material similar to that found in intelligence tests.

OBSERVATIONAL LEARNING

Nearly all of the previous studies have involved learning in one-person situations. A vast amount of learning occurs, however, in social situations where the child himself remains inactive but is able to view the efforts and effects of adults and peers as they engage in activities with objects and with each other. Such learning is described by such terms as *observational learning* or *imitation*. Problems of analysing performance in learning tasks become much more complex when all the variables that operate in a social context must be considered, and, as Bandura and Walters (1963) have pointed out, the principles derived from studies of animal and human learning in nonsocial contexts must be extended and modified, and new principles must be added, if learning in social situations is to be understood. Despite the apparent complexities, progress has been made in the past decade in clarifying many of the basic processes in observational learning. It would be impossible to present within this one chapter an adequate picture of all the ramifications of this research, but since many of the issues are discussed extensively in other chapters, the discussion here will be limited to a review of studies that have examined the conditions under which observational learning occurs and the variables that play an important role in determining its manifestation in performance.

In Discrimination Learning

Wilson (1958) was interested in determining whether preschool children are able not only to learn to imitate the responses made by an adult model but also to make the appropriate response in the absence of a model.

After an initial stage in which the child learned to imitate the model's choice of one of two identical containers, two containers differing in shape and color were introduced. The model consistently chose one of the containers for eight trials and then left the room, after which the game was resumed without the model. The experimental Ss learned the discrimination much more rapidly than a control group given standard discrimination learning trials throughout the study. Thus, even though they had not been instructed to do so, the children had learned the nature of the critical cues while imitating the model's choices.

McDavid (1959) found somewhat less positive results when Ss were rewarded consistently for imitating a model's choices of one of two objects. On trial 1, only 28% of the preschool Ss made an imitative response, and after 24 trials, 44% had not learned an imitative solution to the problem. The task differed from that used by Wilson in two important ways: the child never saw whether the model received a reward for his choice, and the color and position cues of the objects were irrelevant for solution. Thus learning to imitate was more difficult when the model's responses were not differentially associated with an external cue and when the results of the model's choice were unknown to the Ss. The number of imitative responses did increase across trials, and there was a significant interaction between sex of S and age of S. Imitation scores for older preschool boys were lower than those for younger preschool boys, but the scores for the girls increased with age. It was assumed that this interaction was related to the fact that boys more than girls progressively are taught to become more independent as they become older.

The implication that imitation would be less frequent when the model's responses were not associated differentially with environmental cues was investigated directly by McDavid (1962). Four-year-olds were tested in a three-choice discrimination learning task in which an imitative response was rewarded, but the consistency of the model's behavior varied. The model consistently chose one of the three stimuli for one group of Ss, chose one stimulus two-thirds of the time for another group, and one-third of the time for a third group. The frequency of imitative behavior increased as the model's behavior became increasingly

consistent. The proportions of Ss meeting a criterion of six successive imitative responses were 90, 50, and 10 in three groups, respectively. An increasingly strong tendency to ignore the model's behavior was apparent as the conditions required greater degrees of attention to the discriminative cues.

A much more extensive series of responses were made by the model in a study by Bandura and Huston (1961). During the course of responding in a two-choice discrimination problem, the model exhibited verbal, motor, and aggressive responses that were irrelevant to the learning task. There was a high frequency of imitation of the incidental behavior, for example, 90% of the Ss imitated the model's aggressive response (knocking a doll off one of the discriminative stimuli) and 45% marched toward the stimuli in the manner performed by the model. Prior to the experimental session, half of the Ss had been exposed to the model for two 15-minute sessions in which the model behaved in a very nurturant manner, and half had been treated in a non-nurturant fashion. The frequency of imitation of the incidental responses was greater following the nurturant than non-nurturant interactions, but these conditions did not significantly influence the frequency with which the Ss imitated the model's choice of the discriminative stimuli. Partial support was obtained for a positive relation between the child's dependency as rated from observations of social interactions in the nursery school and frequency of imitative behavior, the correlation was significant for imitative verbal behavior, but not for the other categories.

The same task was used by Bandura, Ross, and Ross (1963b) to study the effects on imitative learning of the role adopted by the model. Two adults served as models, and before the discrimination learning task was introduced, an attempt was made to establish a different role for each adult. One adult was the controller and dispenser of resources, for example, he "owned" the toys and dispensed cookies and juice. The second adult assumed the role of consumer and was the recipient of the controller's favors. In a second situation, the Ss were the recipients and the other adult was ignored by the controller. During the discrimination learning task each adult exhibited a different set of novel, irrelevant verbal and motor responses while making his choices.

There was a greater tendency for the Ss to imitate the model who had been the controller of the resources, regardless of whether the other adult or the Ss themselves had been the recipient of the rewards, than to imitate the adult who was the child's rival as the consumer of the resources.

In a final study of the type, Fletcher and Orr (1967) found that observation of the correct choice in two-choice discrimination problems was relatively ineffective unless the Ss were required to point to the stimulus that was correct. No model was used in this study and the information about the response that was correct was provided by a signal light in front of each object.

Variables Influencing Observational Learning

Verbalization is another active form of response that may aid observational learning (Bandura, Grusec, and Menlove, 1966). Observational learning was more effective when the Ss verbalized the content of the observed behavior than when the Ss observed passively or were engaged in competing symbolization. The Ss watched a short film in which an adult displayed a series of novel patterns of behavior and used play materials in unusual ways. The Ss were instructed to verbalize the model's actions as they occurred, to count as they watched the film, or merely to pay close attention. When the Ss later were asked to demonstrate all the model's responses they could recall, the highest scores were obtained by the Ss who had verbalized while the model performed. The Ss who had been instructed to count obtained significantly lower scores than the passive observers, apparently reflecting an interfering effect of the competing verbalization. Half of the Ss had been tested under an incentive set in that they were told they would receive candy for each correct description, but these Ss did no better than did Ss who had not been given such a promise.

The results of another study (Rosenbaum, 1962) indicated that verbalization does not necessarily have to be made by S for recall to be improved. Recall of the names of objects was better when a peer or an adult verbalized the names of the objects in the presence of an attentive but silent S than when there was no verbalization.

The effects on children's imitation of the sex of the model and attentiveness of the

model were studied by Rosenblith (1959, 1961). Before the study, kindergarten Ss were given the Porteus Maze test. In the experimental sessions, models of each sex were assigned to children of each sex, and for the first 10 minutes the model either maintained an attentive interaction with S or terminated it after 5 minutes and spent the rest of the time reading a book. At the end of this period, a maze the child previously had failed was presented to the model, who traced it slowly and correctly. The child, who had observed the model, then was given the maze. This procedure was followed for several different mazes. Observing a model was more effective than having additional trials with mazes in improving maze performance, and prior attention from the model resulted in greater improvement than did withdrawal of attention. Improvement was greater in boys than in girls, and the male was more effective than the female model. But these general statements must be qualified by the presence of significant interactions among the variables. Moreover, the second report made clear that the type of imitative response was also an important variable. A different constellation of results appeared when the measure was choices of a pencil of the same color the model used in completing his maze than when the measure was improvement in tracing mazes.

As part of a larger study, Hetherington (1965) investigated children's imitation of parental choices of objects. The parents, and then the child, was asked to point to pictures in a set of 20 pairs that he thought were the prettier. The Ss were 4- to 5-, 6- to 8-, and 9- to 11-year-olds. The interesting feature of the results was that the incidence of imitation was greater for the parent who had been evaluated as being the dominant member of the family rather than for the parent of the same sex as the child, as might ordinarily be expected.

Fifth graders who were rated as being above and below the median in self-esteem as measured by a paper-and-pencil test of self-evaluation were used by Gelfand (1962) in a study of imitation of preferences. Before introducing the experimental task, the Ss were subjected to failure or success experiences by receiving higher or lower scores than a companion in four learning and performance tasks. The second child then unwittingly

acted as a confederate in a matching test by following a cue provided earlier by the experimenter as the basis for making his choices. Self-esteem was not a significant variable in determining the number of imitative responses made by the Ss, but the frequency of imitation was significantly higher for Ss who had experienced failure than it was for the control Ss or those who had been successful in the first phase of the study.

To test whether the likelihood that behavior will be imitated is influenced by the consequences that follow the model's choices, Barnwell and Sechrest (1965) tested pairs of Ss in grades 1 and 3 under different conditions of reinforcement. One child was designated the model and was seated at a table with toys. He was asked to choose a toy to play with and after a period of time was praised or criticized for his efforts. The S, who had observed this sequence of events, then was asked which toy he wished to play with. When S was busy with his choice, the model was asked again which toy he wanted to play with. For first graders, the tendency was equally great in the observer and in the model to choose the same toy when the model was praised and to choose a different toy when the model was criticized. At the third grade, both Ss chose the same toy with equal frequency when the model had been praised, but the observer tended to choose the toy that had been chosen by the model, even though the model's play had been criticized, and, in fact, the models themselves chose the original toy as frequently as a novel toy. Thus the effects of success on imitative choices were roughly equivalent in all cases, but differences were found in the effects of direct and vicarious punishment at the two grade levels.

Another approach to this problem was taken by Kobasigawa (1965), who used a lever-pulling task and either allowed an adult performer to succeed in completing the defined goal or blocked his performance one-fifth or nine-tenths of the distance from attaining the goal. The Ss, first-grade boys, were asked to push a button that turned off a buzzer signaling the onset of each trial. The results were very similar to those found when the performances of Ss themselves were blocked in these manners. The amplitude and speed of Ss' button-pushing responses were greater when the performer was blocked near the

goal than when he was far from success or was allowed to succeed. The strength of this effect was not influenced by the relation between the performer and the child established before the task by means of supportive or nonresponsive reaction to Ss as he played games with the experimenter.

Direct and vicarious effects of a shift in magnitude of reward on performance of kindergarten Ss in a lever-pulling task were investigated by Bruning (1965). For 30 acquisition trials Ss received either one or five pieces of candy and on 30 subsequent trials the level of incentive was either maintained at the original level or shifted to the alternative level. The Ss performed the task alone, or they observed during the first 30 trials and performed during the last 30 trials. Response speeds were faster with the lower level of incentive and a shift from a high to a low level of incentive produced increased speeds of response. The results were the same whether the S was an observer or a performer during the initial set of trials. Reward to one child affected not only his performance but also the subsequent performance of an observer who was present in the situation.

Baer and Sherman (1964) have shown that social reinforcement of imitative responses may result in the generalization of imitation to a response that was never reinforced. A highly novel procedure was used in this study. Preschool Ss were introduced to a talking puppet, which engaged them in conversation and induced them to imitate such behaviors as head-nodding, mouthing, and making strange verbalizations. The puppet praised the Ss for their performance and in the course of subsequent interactions began pressing a bar. Nearly two-thirds of the Ss demonstrated imitative bar-pressing and later, when reinforcement no longer followed the other imitative responses, extinction of imitative bar-pressing occurred.

Aggression

The study of imitative learning was extended by Bandura, Ross, and Ross (1963a) to a consideration of the learning of aggression through exposure to aggressive behavior in real-life models and as depicted in films by adult models or a cartoon character. In each case the models exhibited a wide range of verbal and physical aggression. After this

exposure, the Ss (preschool children) were mildly frustrated by having some toys they were playing with taken away, and then they were led to an experimental room, which contained many of the objects that had been used by the model in displaying aggression. Exposure to filmed aggression, as well as to real-life aggression, increased the Ss' aggressive responses. All three experimental groups displayed more imitative aggression than did the control Ss who had not seen the film, and the effect was equally strong with Ss who had been exposed to aggressive models in person and in film. There was more imitative aggression by boys than by girls, and by Ss exposed to a male than to a female model. Hicks (1965) repeated the study, using films depicting male and female adults and male and female peer models. The male peer had the greatest immediate influence as a model for imitative aggression, but the adult male had the most lasting effect, as reflected in aggression scores obtained by the Ss after a 6-month interval.

Bandura, Ross, and Ross (1963c) found that preschool children displayed more imitative aggression after they had seen an aggressive model rewarded for his aggression than when the model was punished or no specific consequence followed the aggression. The potential power of observation as a means of acquiring complex forms of social behavior is clearly demonstrated in this series of studies.

Comments

Young children obviously are capable of learning to imitate the behavior of others and, in the course of doing so, of acquiring relevant information about the characteristics of the environment in which the imitative responses were made. Observing the consequences of a model's responses appears to influence the behavior of the child in a manner similar to that which occurs when the child has like experiences in the course of his own performance. Once another person is introduced into the learning situation as a significant participant, a host of variables that have received little attention in other studies of learning take on critical importance. The relation between the model and the child, the role adopted by the model, and the personality characteristics of the child are examples of the types of variable that seem to influence

the degree to which observational learning occurs. It is likely that learning in what may appear superficially to be one-person situations also is subject to the effects of these variables.

CONCLUDING REMARKS

Although an attempt was made in this review to include topics currently receiving primary attention from developmental psychologists interested in children's learning, several potentially important topics have been omitted. Research on learning in school settings is perhaps the most glaring omission. There are two reasons why these studies have not been discussed. First, the studies usually have been undertaken in the context of projects on curriculum development or the use of mechanical and electronic aids in teaching and appear at present to have greater implications for education than for developmental psychology. Second, although many studies of school learning are under way, so few have been published that their importance for the psychological analysis of children's learning is difficult to ascertain. Another omission is the study of learning disabilities in children. These, and studies of learning in the mentally retarded, constitute a large body of research, and the only justification for their omission is that there was neither time nor space.

It has been difficult to decide which articles to include within each topic. Biases and preferences undoubtedly play a part in determining choices, but the goal was to include the most relevant and soundly executed studies that could be found. In some cases isolated but important studies have been omitted because there was no context in which they could be discussed.

What impressions remain after reviewing the literature? First, a strong impression is that a great deal has been done in a very short time. If the energetic pace of the past decade is maintained or accelerated, we soon should have a good grasp of how numerous variables influence children's learning. Studies completed more than 15 years ago seem to have done little more than set the stage for the recent work. The earlier studies provided interesting and useful normative and descriptive data and illustrated many of the ways in which children's performance might differ from that

of animals and human adults. As more and more of these differences have been uncovered, the influence of theories based on research with animals and adults has tended to decline in importance as descriptive influences on research with children.

Munn (1954, p. 449) concluded in his earlier review that, apparently, "the phenomenon of learning is fundamentally the same whether studied in the animal, child, or adult." It is probably impossible to devise situations that would critically test this conclusion. Even if it were correct in the broadest sense, many variables have been found to have differential effects on children's and animals' or adults' performance. In fact, variables often have different effects with children at different developmental levels. Such findings greatly add to the difficulty of the task of theory construction. It seems fair to say that no theory has survived the onslaught of the accumulated data. Different theoretical positions are capable of handling small amounts of the data, but none is effective in handling a significant portion of the results. Frequently, the behavior of very young children can be predicted from S-R models, but it is often easy to modify the task so that their performance violates the predictions that have been made. There was hope that the addition of mediation mechanisms would make it possible to predict the behavior of older children in S-R terms, but the results have offered only partial support for the utility of such constructs. Obviously, new approaches to theory construction are needed, and hopefully these will depart from the framework of traditional learning theories and incorporate a consideration of the role of developmental processes in learning.

After reading these studies, one is not impressed by statements implying nearly total malleability of the child. It is always possible to criticize studies by saying that the tasks were artificial or were inappropriately presented, however, there are too many instances in which learning did not occur or in which variables were ineffective to permit the assumption that other techniques would have permitted any child to discover and perform the correct response. For example, verbal instructions, incentives, models, and degree of training may be important factors in producing correct response at some ages or in some

children, but such factors as the developmental status of the child, his past experiences, and his motivational state may place important restrictions on the degree to which the experimental variables can influence the child's performance.

What are the most salient features of children's learning? A brief statement cannot be adequate, but a number of points can be made. Learning occurs from the time of earliest infancy and at all ages there are large individual differences in the rate of attaining the correct response. The individual differences cannot be attributed to any single characteristic. Intelligence, which would seem to be a likely basis for such differences, especially among older children, proves to be a significant variable but is capable of accounting for only a moderate portion of the variability found. Children's motivation to learn appears to be very high, at least with these children, usually from middle-class families, who typically constitute the samples of Ss included in the studies. The high motivation does not appear to be strongly dependent upon a desire to obtain material rewards, for it is difficult to produce differences in performance by manipulating incentive conditions, except when the responses are already well learned or the Ss have been subjected to conditions of deprivation. This is not to say that the consequences of response do not have important effects on learning. Rather, the most important consequence appears to be knowledge of the correctness of response. After infancy, pleasing the experimenter and, later, pleasing themselves seem to be the most important incentives for children's acquiring the correct response biases and stimulus preferences, which, has been used, its influence in producing correct response appears to be due to its increasing the child's attention to the task.

Verbal instructions, the most common means by which adults attempt to impart information, do not appear to be a highly effective means for controlling the behavior of young children, especially when the effects of instructions are contrasted with those resulting from actual performance or observation of the performance of others. Even young children enter the experimental situation with strong response biases and stimulus preferences, which, if in accord with correct response, lead to rapid learning and otherwise interfere with

performance. Young children seem to be more dependent upon the characteristics of the external situation than are older children. Older Ss are more likely to respond in terms of their own hypotheses and expectations. Such implicit response tendencies may facilitate learning unless they result in the child's overcomplicating or responding inappropriately to the experimental task. Two common obstacles to rapid learning are the child's failure to attend to the stimuli and to determine the critical features by which the stimuli differ. Once appropriate attentional and discriminative habits have been developed, the child can transfer prior learning to a new situation with great ease.

The role of language in learning is less simple than had been assumed. The child appears to go through at least three stages, first, he may not have the words that are necessary to direct behavior, then, he may acquire the words but not use them, and, finally, he may have the words and use them appropriately. The time at which words can function efficiently as mediators of response is probably later than had been assumed, for the performance of 6- and 7-year-olds does not consistently indicate that mediation has occurred. Labeling objects may improve learning by providing a verbal mediator or by focusing the child's attention on the stimuli and emphasizing the differences among stimuli.

Social variables, such as the child's relation with the experimenter, the social milieu in which he has been raised, and his opportunities to use the behavior of others as models for his own behavior, significantly influence the rate at which he will learn. It is doubtful that any task presented by an adult is totally uninfluenced by the operation of social variables. Personality characteristics of the child, most notably his level of anxiety and motivation to achieve, also have a significant effect on performance in learning tasks.

Only a few instances were noted where the experimental studies of children's learning have been utilized in practical situations. Nevertheless, the studies have many important implications for teaching and rearing children. It would be inappropriate to deduce from these studies that the variables necessarily would have the same effects on learning in

everyday situations that they have in controlled laboratory settings. To answer such questions it will be necessary to undertake translational studies in which the effects of the variables are investigated in the context of the practical setting. The attempt in the 1930s to apply the results obtained with mature animals and human adults to the young child led to important lessons in the futility of incautious applications of laboratory research

to everyday life. These settings are similar enough, however, so that experimental studies may be useful sources of information about how to construct tasks and situations that will result in better learning. The extension of interest to practical problems and the continuation of research in the laboratory should produce exciting advances during the next few decades in our knowledge about children's learning.

13. Children's Reasoning and Thinking¹

D E BERLYNE

The problem of defining reasoning and thinking, and thus specifying the boundaries of this chapter, is a formidable one. When definitions of thinking have been offered, they have almost invariably been lacking in precision, and, more often than not, they have borne the stamp of commitment to particular theoretical interpretations. Thought has sometimes been conceived so broadly that it encompasses virtually all conscious or internal psychological processes, as the word so often does in everyday speech ("Penny for your thoughts!") An even more extreme view has maintained that "thought is simply behavior—verbal or nonverbal, covert or overt" (Skinner, 1957, p. 449).

In the history of psychology, there have been two traditions with contrasting views of the role of thinking. The rationalist-spiritualist tradition flourished in continental Europe during the seventeenth to nineteenth centuries. It had a strong inclination, traceable at least as far back as the works of Plato and Aristotle, to emphasize the uniqueness of human thought, its intimate connections with volition, and the determination of behavior by cogitation, understanding, and judgment. The rival empiricist-sensationist-associationist-materialist current, which was particularly strong in Great Britain during the same period and gradually spread over a wider area, tended to regard thought as a derivative of sensation and, to a lesser extent, of action. In the present century a similar division exists, although the two traditions have un-

dergone radical transformations. Members of the Gestalt-cognitivist current see behavior as governed largely by "representations," "models," or "images" of external reality—in other words, by factors akin to thinking. They are, however, less inclined than their rationalist predecessors to treat thought as a prototype of psychological functioning. In its earlier phase, this current tended to characterize thought as a derivative of perception. More recently, its representatives have been greatly influenced by computer analogies and tend rather to analyze thought in terms of storing and processing information. On the other hand, the reflexologists and behaviorists of the early twentieth century and the later neobehaviorists of the S-R or neoassociationist current have been hesitant in assuming that representational processes intervene between stimulus and response. They have done so only when there seemed to be no alternative, and they have treated thoughts as covert or internal responses, derived from overt motor responses.

In this chapter we shall adopt a set of definitions that have been outlined elsewhere (Berlyne, 1965a) and are meant to represent the highest common factor of several approaches that have been proposed. The word *thinking* is applied when behavior can be assumed to depend on a chain of two or more representational or symbolic intraorganismic events. Neoassociationists would classify these events as both "symbolic responses" and "symbolic response-produced stimuli," having a predilection for hypothesizing, as a working assumption, that central events are governed by some of the same principles that govern overt responses and

¹ The preparation of this chapter was facilitated by a grant from the Ontario Institute for Studies in Education.

external stimuli. Others (notably those partial to cognitivist theories) prefer not to adopt such a strategy.

Following suggestions made by such diverse writers as Maier (1929), Hull (1935), and Boiko (1955), we can regard *reasoning* as a process whereby several pieces of prior learning combine to produce a solution to a newly encountered problem. In other words, a new stimulus-response association (using this term in a purely statistical sense) can be assumed to result from the previous acquisition of two or more learned associations that differ from the new association and from one another in their stimulus terms, their response terms, or both.

Not all thinking is reasoning, autistic thinking (e.g., daydreaming) is not. Not all reasoning is thinking, there are several cases of reasoning (e.g., in lower animals) that can be explained by the intervention of a single covert symbolic response rather than a chain of symbolic responses. Any process that satisfies simultaneously the criteria for thinking and for reasoning can be called *directed thinking*.

According to a conceptualization that has been developed on the basis of these definitions (Berlyne, 1965a), *directed thinking* is essentially a process of arriving at beliefs, evaluations, and decisions through symbolization of sequences of transformations and their outcomes. This means that the salient attributes and problems of thinking emerge most clearly when a dynamic situation, involving a succession of changes in the stimulus field, is given representation within the organism. *Directed thinking* helps us out whenever we cannot tell how to react to a given event without identifying the chain of past changes that has led up to the event or the chain of future changes that the event heralds. Even a static situation can be handled in the same way, as we focus on various aspects or properties in turn and keep track of the relations that connect one with another by means of a sequence of thoughts representing transformations. The most unequivocal examples of *directed thinking*, fulfilling the criteria for both thinking and reasoning, are cases of deductive inference, in which two or more thoughts are pieced together to yield a conclusion that could not be reached if any of them were missing.

Other Categorizations

In accordance with the foregoing discussion, this chapter will not deal with many of the topics that developmental psychologists are wont to place under such headings as "thinking," "intellectual development," and "cognitive development" (see Berlyne, 1965, 1966a). For one thing, most of the investigations that have been subsumed under these headings have been studies of "concept formation," "concept attainment," or "concept learning." These, and the somewhat different investigations devoted by Piaget to the development of "concepts" or "notions," are dealt with in another chapter. The usual concept-formation experiment, in which the subject has to distinguish those stimulus objects to which a certain response, verbal or nonverbal, must be attached, involves discrimination learning. Most, but probably not all, of the experimental situations in question have required mediated or secondary generalization and discrimination, that is, the intervention of at least one symbolic response or label. In many cases, the task cannot be completed without recourse to inferential processes involving complicated chains of symbolic responses. So thinking can contribute to concept formation, and concept formation in its turn can indubitably affect the course, and especially the content, of *directed thinking*. But this does not mean that concept formation and thinking are the same thing (see Berlyne, 1966a).

Similarly, numerous phenomena that will not be treated here have been classified as "problem solving." Often this term means exactly the same as concept formation. At other times the term seems simply to cover any kind of learning in which stimuli have to be discriminated from one another or a correct response has to be selected from a set of competing responses. In the absence of an agreed-on definition of what constitutes a "problem," problem-solving does not seem to be a useful category of behavior, and it is especially hazardous to identify it with thinking.

Plan of the Chapter

Since reasoning and thinking are highly specialized and intricate ways of manipulating and responding to symbols, we cannot properly examine them and research devoted

to them without first considering some questions relating to symbolic functions in general. We shall therefore first take up problems, ideas, and findings that concern the origins and development of symbolic functions. Then we shall turn to the development of ideational (that is, symbolic) control over behavior, of which rational control (control through reasoning) is a particular form. After these preliminaries we shall be in a position to look at work concerned directly with reasoning and thinking in the child and, finally, to glance at some of the much neglected motivational aspects of these functions.

ORIGIN AND DEVELOPMENT OF SYMBOLIC FUNCTIONS

Communicative and Representational Functions

Symbolic responses (in the form of speech, gestures, facial expressions, writing, and actions that create symbolic artifacts) often have a primarily *communicative* function. They are, in other words, used to influence the behavior of other human beings or animals. On the other hand, the symbolic responses with which we are concerned are used *representationally*. The organism that produces them uses them to influence its own behavior. Overt symbolic responses, which give rise to publicly available stimuli, can work in both of these ways at once. However, except in very early childhood, the representational function in human beings is performed mostly by internal symbolic responses, which can affect only the originator's nervous system. Covert representational responses come to predominate, presumably because of the advantages they offer in privacy, lack of repercussions from disturbance of other persons, and relatively low effort.

Various views have been expressed on the relations between the communicative and representational roles of symbols.

Mead (1934), in an account that has had a profound direct or indirect influence on neobehaviorist analyses of intellectual processes, traced the origin of symbolization back to the "gesture," which calls for an "adjustive response" in another organism. The gesture becomes a "significant symbol" when "the individual responds to his own stimulus in the same way as other people respond." This

capacity for "putting ourselves in the place of others" is the source of thought, "for in order that thought may exist there must be symbols, vocal gestures generally, which arouse in the individual himself the response which he is calling out in the other, and such that from the point of view of that response he is able to direct his later conduct."

Much of contemporary Russian developmental psychology bears the imprint of Vygotski's (1934) view, which, although it has a distinct Marxist tinge, has much in common with Mead's. The "use and creation of implements of labor although present in embryonic form in some species of animals, are a specific characteristic of the human process of labor" (p. 48). This capacity gives rise eventually to the elaborate economic activities that characterize human societies, and these, in their turn, require collaboration and therefore efficient communication, which is ensured by language. The child has to learn to speak to others and to respond appropriately to what he hears others say to him. Gradually language, which originates as a means of social control, turns into a means of self-control. The child masters the use of his own verbal responses, particularly in the form of "inner speech," to regulate his own behavior. The influence of this view in the Soviet Union has been reinforced by Pavlov's emphasis on the "second signal system" or system of learned "connections" involving words (Pavlov, 1932). Human beings learn to respond to words as signals of signals belonging to the "first signal system," that is, as substitutes for nonverbal conditioned stimuli. Subsequently, kinesthetic stimulation from organs of speech is conveyed to the cerebral cortex, and its central correlates play their part in determining action.

Piaget (1947) agrees that the "system of collective signs" that constitutes language "conveys to the individual an already prepared system of ideas, classifications, relations—in short, an inexhaustible stock of concepts which are reconstructed in each individual after the age-old pattern which previously molded earlier generations."

Nevertheless, both Vygotski and Piaget deny that acquisition of verbal communication is the sole source of the internal representations on which thought depends. Vygotski (1934) uses both phylogenetic and onto-

genetic arguments. He points out that chimpanzees possess rudimentary equivalents of human thought and speech. They are capable of elementary reasoning, exemplified by Kohler's (1921) famous experiments on "insight," and they vocalize to express affective states and to achieve "psychological contact with others of their kind." These two functions are, however, quite independent in the chimpanzee. Similarly, Vygotski refers to experiments by C. Buhler (1927) demonstrating insightful problem-solving in 10 to 12-month-old human infants, which are "exactly like those of the chimpanzees." The origins of speech also appear before the first birthday in the form of babbling and utterance of the first words. The first signs of coalescence and interdependence of intellectual and verbal capacities, as a result of which "thought becomes verbal and speech rational," do not appear until considerably later. So Vygotski is led to insist that thought and language originate independently and later come to merge in the kind of internal speech that constitutes much mature thinking.

Vygotski's successors have discerned some corroboration for his statements in an experiment by Bozhovich (cited by Zaporozhets and El'konin, 1964). Children between 3 and 5 years of age had to gain access to a picture, which was attached to one end of a lever, by using a rod to bring the lever nearer. The solution to the problem necessitated first moving the picture away from oneself, which was a source of difficulty. An earlier investigation by Levina had shown how children can at first solve such problems only by motor trial and error. When they are a little older, they can look at the stimulus objects and plan a course of action, which they then implement. Finally, they can plan a solution in the absence of the objects, using words to represent them. Bozhovich instructed his subjects to describe verbally in advance how they would carry out the task. The hope was that this prior verbalization might accelerate the appearance of a capacity for prior planning. Some children were unable to give any verbal description and sought a solution solely through motor activity. Some gave verbalizations that reflected the same mistakes as their actions. Some expressed verbally a solution that they had already dis-

covered. All in all, there was no evidence that the verbalization helped in the discovery of a solution. As Zaporozhets puts it, "Speech did not direct the intellectual process but was itself determined by it." The independence of reasoning and language in development is thus illustrated.

Piaget and Inhelder (1959) cite three arguments in denying that the acquisition of language is solely responsible for the classificatory and ordering "operations" on which logical thinking depends. They refer to studies of deaf-mute children, apparently revealing no serious abnormality in the development of ordering or of elementary classification. Second, Piaget's earlier investigations indicate that, when the child first takes over the language current in his environment, he assimilates it to his own intellectual structures and does not immediately take over the forms of classification implicit in adult speech. Finally, these authors' own developmental studies of logical operations show children to possess the linguistic tools that are necessary for adult logic (e.g., the ability to use quantifiers like "all" and "some") before they can use them reliably to frame correct statements or to arrive at valid inferences.

Piaget maintains strongly that the structures basic to logical thinking originate not in the grammatical training through which a child learns to piece together syntactically correct sentences but in his experience of "coordinating motor acts in sequences for the attainment of practical ends."

Analysis of the Symbolic Function and of Meaning

Many writers have referred to "representations," "symbols," and the like with little or no attempt at definition, evidently assuming that their connotations are self-evident. Others, in contrast, have endeavored to specify with some semblance of precision what constitutes a "sign" or "symbol" and to analyze the relation between a sign or symbol and the object for which it stands (its "significate" or "referent").

These attempts have been extremely varied, but they fall into a few categories. First, an object or stimulus has sometimes been held to evoke imagery or other mental content corresponding to the significate. According to Titchener (1909), "meaning" can

be identified with "context" the meaning of a stimulus or an idea resides in the kinesthetic sensations or images that it evokes and that correspond to stimuli with which it has been accompanied in the past. Ogden and Richards (1923) are responsible for another mentalistic account that at one time enjoyed some vogue. A symbol, they maintained, evokes a conscious experience resembling what would have resulted from the "referent" if it had been present. Tolman's (1932) "sign-gestalt theory" constitutes a neobehaviorist equivalent of the same approach, and variants of it reappear continually. If a stimulus, S_1 , has regularly been followed by another stimulus, S_2 , then S_1 becomes a "sign" and evokes an expectation of the significate, S_2 . But since Tolman believed that all learning, however elementary, consists in the acquisition of expectations or "cognitions" of this sort, such a definition can scarcely serve to mark off a domain of intellectual or ideational activity that can be contrasted with simpler psychological processes.

In contrast, the reflexologists and early behaviorists identified "meaning" with responses. Pavlov (1932) pointed out that innumerable conditioned stimuli can act as "signals" of the relatively few unconditioned stimuli of outstanding biological importance; they acquire their signalling function by frequently preceding or accompanying an unconditioned stimulus and manifest it by evoking responses associated with the unconditioned stimulus in anticipation of its appearance. Words, in their turn, act as signals (belonging to the second signal system) of nonverbal conditioned stimuli. Similarly, Watson (1924) equated meaning with the sumtotal of responses associated with a stimulus object. "'meaning' is just a way of saying that out of all the ways the individual has of reacting to this object, at any one time he reacts in only one of these ways" (p. 250).

This approach has two serious shortcomings. Like the early introspective treatments, it regards "meaning" as an attribute of virtually all stimuli and therefore fails to capture the peculiarities of thinking and other ideational activity. Further, it fails to recognize that a subject's reaction to a verbal or other pattern of symbols is, more often than not, quite different from the reaction that the sig-

nificate would have evoked if it had been present. This is one fact that makes symbols so valuable. Morris (1946) gives the example of a motorist who is told that a landslide has blocked the road some distance in front of him. The communication makes him drive on a little further, until he finds a side road into which he can turn. This is not what he would have done if he had seen an obstruction in front of him.

Neobehaviorists, especially those of the S-R or neoassociationist current, have adopted more complicated definitions, although they still single out responses as the links between sign and significate. Morris (1946) offered an informal paraphrase of his formal definition of a sign as follows: "If something, A, controls behavior toward the goal in a way similar to (but not necessarily identical with) the way something else, B, would control behavior with respect to that goal in a situation in which it were observed, then A is a sign." A sign is defined as a "symbol" if it is produced by its interpreter (i.e., an organism for which it is a sign) and acts as a substitute for some other sign with which it is synonymous.

This analysis has undergone further development at the hands of Osgood (1952), whose definition has been accepted as the best available to date by several writers, apparently including Morris himself (1964). He states that "A pattern of stimulation which is not the object is a sign of the object if it evokes in an organism a mediating reaction, this (a) being some fractional part of the total behavior elicited by the object and (b) producing distinctive self-stimulation that mediate responses which would not occur without previous association of nonobject and object patterns of stimulation." Osgood clarifies this definition with the help of the diagram shown in Fig. 1, which also embodies a theory to explain how stimuli become signs. In this diagram R_T is the overt response pattern associated with S , the significate s is the sign

Fig. 1 Osgood's analysis of the sign-significate relation

which, through conditioning, comes to evoke r_m , a "detachable" portion of R_T (i.e., elements of R_T that can occur in the absence of S). This r_m is the "mediator" (with which the "meaning" of the sign is identified). Then s_m , the stimulus aspect of r_m , evokes R_s , an overt response pattern which may be different from R_T .

Finally, the rather different and more radical proposals of Skinner (1957) must be mentioned, especially in view of the profound influence that this writer has had on recent developmental psychology. He prefers not to speak of signs, symbols, or meaning. Instead, he reduces thinking and intellectual activity generally to "verbal responses," overt and covert. Verbal responses are responses reinforced "through the mediation of a person." There are two ways in which they become connected with the external objects or events that, according to other terminologies, they "represent." A "mand" (e.g., a verbal request or command) is regularly reinforced by the appearance of a particular object or event. A "tact" (e.g., a sentence in the indicative mood or a name) has been regularly reinforced only in the presence of a particular object or event. Skinner's definition encompasses many forms of behavior that would not be considered verbal or symbolic in the usual senses. He is explicitly concerned to minimize the differences between thinking and other forms of behavior, so that his analysis is hardly capable of throwing light on the peculiarities of behavior that are controlled by thought processes.

The essence of the Morris-Osgood approach is the assertion that signs evoke some of the same behavior as the corresponding significates but generally not the same behavior in all respects. Other writers have singled out the ability to distinguish a sign or symbol from what it stands for as an indispensable attribute of the sign-significate relation. In other words, there must be some circumstance in which the subject would react differently to the two. For example, Piaget (1945) says that the "symbolic function" cannot properly be said to exist until the child can tell the difference between the "signifier" and the "signified." This is illustrated by symbolic play. A child may treat a doll as if it were a baby, but in other conditions he makes it clear that he can differentiate between the two.

Similarly, according to Werner and Kaplan (1963), "representation implies some awareness, however vague, that vehicle and referential object are not identical but are, in substance and form, two totally different entities."

Origins of Internal Symbolic processes

There are two major views on the origins of internal symbolic events that can represent external events in their absence. The nineteenth-century associationists, like their empiricist predecessors, thought of "ideas" as faint copies of the sensations produced by stimuli impinging on sense organs. Plato's analogy of the impression left on a piece of wax after a seal has been withdrawn was widely accepted. The Gestalt school protested against this kind of psychology, but the view they favored was nevertheless similar. They spoke of the elements of memory and thought as "traces" of previous perceptions (Koffka, 1935). They contended, however, that a trace corresponds to a perceived pattern or configuration rather than a unitary sensation, which meant that structure and organization were important. Furthermore, they held that a trace undergoes endogenous changes, in accordance with the law of "*Pragnanz*," after it has been freed from the influence of its parent stimulus pattern. These changes generally turn it into a distorted representation, rather than a copy, of the parent pattern.

Other theorists, representing a surprising variety of traditions, have contended, on the other hand, that internal symbols derive from motor responses. The relatively late appearance, both phylogenetically and ontogenetically, of symbolic functions seems to them to argue against simple impressionability of the nervous system as a basis for these functions. Since particular thoughts are usually evoked by external stimuli and prior thoughts, it seems defensible to refer to them as "internal" or "implicit" responses. Whether thoughts are separable from activities of muscles and glands has been debated since the days of early behaviorism (see Humphrey, 1951). But even if they do not conform to the older and narrower definition of a response, they seem to qualify clearly enough as responses in the broad sense, that is, as events that can become associated with stimuli through learning (Miller and Dollard, 1941; Berlyne, 1965).

A hypothesis that has suggested itself to several writers is that internal symbolic responses are derivatives of motor responses that have become associated, through learning, with their significates. This hypothesis has, in fact, appeared in three distinguishable variants

1 According to one view, thought elements can be identified with minute contractions, or perhaps only action currents, in muscles. These are insufficient to produce visible bodily movement but can supply kinesthetic stimuli to evoke subsequent responses (Watson, 1924, Washburn, 1926). Naturally, subvocal reactions of the speech organs have received most attention. But Watson, the outstanding spokesman of this view, recognized that attenuated reactions of the muscles subserving manual responses and of the muscles and glands of the viscera may also participate in thinking. This approach has, from time to time, encouraged statements to the effect that we think with the whole body rather than with the brain alone.

2 According to a different view, thought elements consist of neural processes that, if allowed to complete themselves, would lead to innervation of muscles but are cut short before motor pathways are reached. For example, Sechenov (1878) depicted a thought as a truncated reflex: inhibition prevents the final or motor segment of the reflex arc from coming into play. The sensory and central phases of the reflex occur alone, or, when a thought is evoked by another thought, the sensory as well as the motor phase may be lacking.

Piaget's (1949) scheme takes account of the reciprocal action between the organism and the environment. Originally, the organism does something to produce an environmental change, and this in its turn generates stimuli that act on the organism. Thought uses "internalized" versions of this process, whereby the motor act and the external environment are eliminated from the circuit. The neural process that used to produce the motor act leads directly to the neural process that would have resulted from the external stimulus.

3 A view developed by Hull (e.g., 1931) and made more explicit by Osgood (1953) holds an internal symbolic event (Hull's "fractional anticipatory goal response," (Osgood's

"mediator") to consist of some components (which may or may not be reduced in amplitude), but not others, of a complex motor pattern evoked by the significate. But which components will occur in anticipation of, or in the absence of, the significate and thus serve to represent it? Osgood, following Hull, suggests that they will be the "detachable" components—those that are capable of occurring without the significate. This writer (Berlyne, 1965) has argued against such a view, suggesting that they will be component responses that do not delay or jeopardize subsequent reinforcement by occurring before the significate has been reached and that are thus relatively insusceptible to inhibition of delay.

These three variants are, of course, not mutually exclusive, so that there may be some truth in all of them.

Whatever form it takes, the reduction, attenuation, or internalization of a response has often been ascribed to the "law of least effort," "principle of reactive inhibition," and the like. There seems to be a deeply rooted tendency, which makes obvious biological sense, for an organism to perform a response with the least degree of vigor that is compatible with fulfillment of its function. Rats trained to press a bar in a Skinner box will gradually reduce the force that they exert until they reach the point beyond which reward will not be forthcoming (Skinner, 1938). Sequences of motor acts will sooner or later degenerate into brief gestures if these will do just as well, the most familiar example being the threatening gesture. The relevance of this phenomenon to communicative symbolization has been pointed out by Mead (1934) and by Mowrer (1954). The same kind of process can go much further when symbols are used representationally, since they then need to have sufficient intensity to preserve their stimulus value but need not be strong enough to affect the external environment.

Hull (1930) referred to "acts whose sole function is to serve as stimuli for other acts" as "pure stimulus acts." These became the "cue-producing responses" of Miller and Dollard (1941) and the "mediators" of Osgood (1952). In a strikingly similar vein, Vygotski (1960) made much of situations in which "the stimulus created by man himself determines his reaction." As illustrations, he cites tying

a knot to remember something and casting lots to resolve a conflict. This is the root of "mastery of one's own process of behavior." The transition to mediating activity radically reorganizes the entire mental operation, as the use of a tool modifies the natural activity of organs and endlessly extends the system of activity of the mental functions. The former and latter together we designate by the term of *higher mental function or higher behavior*."

Some important aspects of the sign-significate relation can also be clarified by use of information-theoretic language (Berlyne, 1965, Chap. 1). There must be some degree of correlation or contingency or correspondence (not necessarily of similarity) between properties of the sign or symbol and properties of the significate. This implies that the sign or symbol contains information transmitted from the significate. It does not, however, mean that the properties of the significate must be causally determining the properties of the sign. The correlation between the two can be brought about indirectly through other factors, including some belonging to the distant past. Then, since a symbol plays some part in determining the response, information contained in the symbol (including some that comes from the significate) is transmitted further to the motor organs. In this way, the symbol acts as an intermediary to ensure the transmission of information between the significate and the response, even though the significate may be outside the stimulus field.

Images, Words and Other Symbols

The kinds of internal symbols discussed most often are imagery and silent speech. Properties of images and covert verbal responses must, of course, be treated as intervening variables and be inferred from overt behavior (see Berlyne, 1965a).

The old-fashioned belief that the image is simply a trace left by an external stimulus has not survived closer inspection, so that the genesis of the image is now generally regarded as a gradual and complicated process. Piaget (1945) has characterized the image as "internalized imitation." He traces the development of imitation in the child up to the point where "deferred imitation" (i.e., imitation of a remembered model that is no longer present) appears in the course of the second year. He finds the first indications of imagery at

about this time and concludes that the two functions are intimately related. Imitation is, however, strongly biased toward "accommodation" (i.e., toward letting behavior be governed by properties of external objects). Another fountainhead of imagery, and of representational thought generally, is "symbolic" play or "role-playing." This, being essentially "assimilative" (i.e., determined by processes within the organism that are independent of the present external environment), compensates for the stimulus-bound nature of imitation. It provides an element of emancipation from the external environment and thus helps to establish the necessary equilibrium between accommodation and assimilation.

Piaget's (Piaget and Inhelder, 1967) more recent investigations of imagery contrast images of static situations with images representing the transformations that lead from one of these to another. The latter are mastered later than the former, since they must await the formation of the "operational" structures through which systems of transformations are handled in thought.

Other investigations (see Berlyne, 1965a) likewise draw attention to the complex, dynamic nature of imagery and its dependence on imitative and receptor-adjusting responses. Zaporozhets (1958), in particular, has dwelt, both theoretically and experimentally, on the way in which patterns of eye movements and manual exploratory responses correspond to spatial properties of external stimuli. Since they reproduce shapes and geometrical relations characterizing external objects and events, they can represent them in their absence.

The acquisition of linguistic symbols is a vast domain of developmental psychology in itself and is dealt with elsewhere in this *Manual*. However, we may note here Piaget's observation that both words and images begin to control behavior, and are mastered, at about the same time—toward the end of the second year—because the ability to speak, like the ability to imagine, depends on deferred imitation.

Several writers would, however, protest against any suggestion that thinking is confined to, or even dominated by, verbal and imaginal symbols. Both Sechenov's and Piaget's work bring out the dependence of directed thinking on organized sequences of internal

symbolic events that correspond to, and thus represent, sequences of transformations. Trains of thought could not preserve their correspondence with reality and their internal consistency if all they did were to represent one stimulus situation after another. They also have to represent the transformations, whether they be physicochemical processes, logico-mathematical steps, or legal moves, that could lead from one represented stimulus situation to the next.

The motor acts that lead in a regular, predictable manner from one stimulus situation to another fall into two main classes. These are *executive* responses, which produce physical changes in external objects, and *receptor-adjusting* responses, which cause sense-organs to leave one combination of stimuli and focus on another. It is interesting that Piaget (e.g., 1949) singled out executive responses and Sechenov (1878) singled out receptor-adjusting responses as the raw material out of which the internalized elements of directed thinking are fashioned (Berlyne, 1965).

✓ Stages in the Development of Symbolic Functions

Various aspects of the development of representational functions have been brought into focus by writers belonging to different traditions. This is an area of inquiry in which everybody is likely to show a particularly strong attachment to his own classificatory schemes and terminological creations, so that a consensual synthesis is still some way off.

Piaget (1947, etc.) has provided the most thoroughgoing account. During the *sensorimotor* stage, which occupies roughly the first two years of life, the child gradually masters those forms of adaptive interaction with external objects that are possible without symbolic mediation. Nevertheless, the primitive rudiments of symbolization—the first signs of an ability to take account of the properties of an object that is outside the stimulus field—appear during this period. For example (Piaget, 1937), by about the tenth month the child has attained the notion of an external object that does not go out of existence when it goes out of sight and does not change its characteristics when it changes its appearance. He looks for objects after they have disappeared from view and knows where he is likely to find them. Even earlier than this, he

shows expectation of events that have not yet occurred, when signals that have regularly preceded them are perceived. During the *sensorimotor* stage, perceptual “anticipations” and “perseverations” emerge, enabling the child to make comparisons between objects that are perceived successively rather than simultaneously. By the end of this stage, forms of “insightful” problem-solving, comparable to those achieved by Kohler’s apes, are possible and constitute the highest levels of adaptation that behavior can reach without drawing on the resources of uniquely human symbolic capacities.

Like other writers, Piaget places roughly toward the end of the second year the great turning point when behavior comes under the control of words, images, and other symbolic processes. This is when thought becomes a major determinant of activity. During a *pre-conceptual* stage (roughly 2 to 4 years), the child possesses only precepts. The notions of class-membership and class-inclusion are lacking, so that, to cite one of Piaget’s examples, the child regards every snail he sees as an instance of “snail,” that is, of the combination of properties constituting “snailishness.” Whether the same snail keeps on reappearing or there are several distinct, but similar, snails is hardly a meaningful question. The child does not understand that every snail is a member of a class of snails, having some characteristics in common with all other snails as well as unique characteristics that confer on it its individuality. These limitations diminish during the *intuitive* stage (4 to 7 years). Class-membership and class-inclusion now exist, as evidenced by the ability to form sentences containing quantifiers like “some” and “all.” But these words are often used to state incorrect conclusions.

At about age 7, the stage of *concrete operations* begins. Thinking now makes use of “operations,” defined (Piaget, 1953) as “actions which are internalizable, reversible, and coordinated in systems characterized by laws which apply to the system as a whole.” The laws in question define organized systems of operations such as the “grouping” (*groupe-ment*) invented by Piaget himself, and others familiar to mathematicians like the “group,” the “semilattice,” and the “lattice.” With the help of these structures, the child is able to handle classification, ordering, and number.

This means that elementary forms of logical and mathematical reasoning are available

Finally comes the stage of *formal operations* (beginning at about age 11 and complete by about 15), during which additional structures, necessary for advanced logical, mathematical, and scientific thinking, are completed. Formal operations are "operations on operations." Through them, relations between abstract entities can be manipulated.

Ivanov-Smolenski (1956, 1963) was an outstanding pioneer among Pavlov's students in extending classical conditioning techniques to human children and particularly in investigating the relations between the first and second signal systems. He suggested a four-fold sequence. First comes the formation of "direct-direct" connections, that is, conditioned associations in which both stimulus and response are nonverbal. Then "verbal-direct connections" attach nonverbal responses to verbal stimuli. "Direct-verbal connections" (between verbal responses and nonverbal stimuli) come later, reflecting the well-known fact that the ability to respond to words is generally in advance of the ability to utter them appropriately. "Verbal-verbal connections" are the last to appear, and these constitute the interverbal associations on which thinking depends.

Gal'perin's (1954) description of four stages characterizing the learning of "every mental action" has had an enormous influence on recent Soviet psychology and has, in fact, inspired several innovations in teaching practice. The child has initially to master an action by interacting with concrete objects. This includes the learning of the necessary discriminations and the perfection of skilled movements. Next, the action must be transferred to the plane of "audible speech." The child learns to use words appropriately while in contact with the relevant external objects. "When a full reflection of a material action has been achieved on the plane of audible speech, the stage of transference to the mental plane begins." He then uses language and images "in his head." As a final stage, the action "in the head" is "abbreviated or compressed" and otherwise "consolidated" as a "mental action."

Werner and Kaplan (1963) describe the "primordial" symbol-situation as an intimate "sharing" relation bringing together four com-

ponents, the addressor (or originator of the symbol), the addressee, the referent, and the symbolic vehicle. Ontogenesis is marked by progressively increasing "distancing" or "polarization." The person, whether addressor or addressee, becomes more and more distinct from the referent, as does the person from the symbolic vehicle, the symbolic vehicle from the referent, and the addressor from the addressee.

According to Bruner (1964, 1966a), the child first masters "enactive" representation (representing events through appropriate motor responses). He then becomes capable of "ikonic" representation, which "summarizes events by the selective organization of percepts and of images, by the spatial, temporal and qualitative structures of the perceptual field and their transformed images." Finally comes "symbolic" representation, which "represents things by design features that include remoteness, arbitrariness," the prime example being linguistic coding. An illustrative experiment was performed by Bruner and Kenney (1966), who confronted children ranging between 3 and 7 years of age with 9 beakers arranged in a matrix, arranged in order of increasing height from front to back and in order of increasing width from left to right. Over half of the children could replace beakers that were removed from the display and reproduce the whole arrangement when all had been removed. These tasks are held to require ikonic representation, since the children have to "copy" something they have in mind. A transposition task in which a beaker that used to be in one corner is placed in another corner, so that the whole matrix has to be rotated, was not accomplished by 50% until they reached 7 years. This task appears to require verbalization of the relations governing the arrangement.

Since the words "ikonic" and "symbolic" have been used in connection with quite different classifications of sign processes, notably by Morris (1946), this writer (Berlyne, 1965) has suggested that the words "schematic" and "onomastic" be substituted for them. He has suggested further that the differences between Bruner's three forms of representation can best be specified in terms of "informational correspondence." As noted previously, there must be some degree of

correspondence or information transformation between the nature of a sign or symbol as a whole and the nature of the significance as a whole. Informational correspondence [the opposite of Garner and McGill's (1956) "interaction uncertainty"] can be said to exist if there is some degree of correspondence of information transmission between particular parts or properties of the sign or symbol and particular parts or properties of the significance. From this point of view, enactive symbols possess informational correspondence with motor patterns, schematic (Bruner's "ikonic") symbols possess informational correspondence with external stimulus patterns, and onomastic (Bruner's "symbolic") symbols possess informational correspondence with neither.

DEVELOPMENT OF IDEATIONAL CONTROL OVER BEHAVIOR

Ever since Plato and Aristotle, reason and volition have been closely linked by philosophers. And at least since Descartes, an intimate connection, frequently amounting to identification, has been seen between thinking and consciousness. Abstruse and acrimonious debates have, of course, raged around these concepts for centuries. Awareness of what one is doing and why one is doing it was long regarded as a distinguishing mark of "rational" or "intelligent" behavior, through which it could be contrasted with behavior governed by "instinct" or "reflexes."

Even those who are primarily interested in publicly observable behavior and wish to steer clear of metaphysical arguments must recognize important and outwardly manifest differences between the kinds of behavior that are and are not amenable to control by ideational processes, that are and are not voluntary, that are and are not said to be accompanied by awareness. If the first of these characteristics is present, the other two seem generally to be present too. It is possible to base such distinctions on objective criteria—on attributes or accompaniments of the behavior that are fully accessible to an external observer—regardless of whether the philosophical connotations of "reason" or "will" (particularly "free will") are applicable or whether what we are calling "awareness" corresponds to consciousness in the sense of subjective experience.

We must therefore consider, with special attention to their developmental aspects, the distinctive characteristics of behavior that is "rational" (in the sense of subject to the influence of thinking and reasoning), accompanied by "awareness" (the use of which term might avoid the special connotations of "consciousness"), and "voluntary."

Awareness

Dollard and Miller (1950) have suggested that, from a behavioral point of view, the unconscious is the "unverbalized." In this they were echoing Freud's (1915) statement that repression prevents ideas from becoming conscious by denying them "translation into words."

Eriksen (1960) has objected to this view. He points out that "one's verbal description of the facial appearance of another individual may be wholly inadequate in enabling another to recognize this person among a crowd. However, if the person giving the description possesses a mediocre artistic talent, it will be possible for him to draw a sketch of the person described which would greatly increase the chances of the individual's being recognized." If we "adhered strictly to a definition of awareness in terms of verbalization," he says, "we should have to conclude that somebody capable of a portrait but not of an adequate verbal description was not aware of the appearance of the person in question." It is noteworthy, however, that sketching is a form of symbolic behavior, so that Eriksen's criticism might be overcome if we recognized the hallmark of awareness to be symbolic representation, usually in verbal form, but occasionally in the form of nonverbal symbolic responses such as drawing, imitation, gestures. Since directed thinking (Berlyne, 1965) controls behavior through symbolic responses, it is easy to see why stimuli and motor activities that are deprived of symbolic representation cannot come within its purview.

East European writers have likewise attached great importance to whether or not stimuli and motor responses are, as they put it, "reflected in the second signal system." Ivanov-Smolenski (1949, 1951, 1956) has reviewed relevant experiments carried out in his own laboratory.

For work with children, Ivanov-Smolenski

ski's group has made much use of motor conditioning with verbal reinforcement. In this technique the response consists of pressing a rubber bulb with the hand, and the unconditioned stimulus is the word "Press" uttered by the experimenter. If the unconditioned stimulus is preceded by a light, a sound, or some other conditioned stimulus, this conditioned stimulus will normally come to evoke a conditioned anticipatory press. After the first conditioned response has appeared, reinforcement is usually maintained by saying "Right!" or "Wrong!" Differentiation can be set up by having two conditioned stimuli and saying "Don't press" after presenting the one that is to become inhibitory.

In some of the experiments, child subjects have been questioned after training. It is reported that the youngest children can describe the stimuli and the response correctly but cannot report the connection between them. Then comes a stage when positive or excitatory connections are correctly reported but the significance of a negative or inhibitory stimulus is not. Verbal reports then either fail to reflect the fact that the subject reacted differently to the two stimuli or assert that he refrained from making the motor response to the negative stimulus when he did not. It is interesting that, even when differentiation is fully reflected in the second signal system, the presence of the conditioned stimulus is generally not reported when an extraneous stimulus, productive of external inhibition, accompanies it.

Other experiments show that a stimulus may be sufficiently intense for the first signal system but not for the second. Kotliarevski used a slight increase in illumination as a conditioned stimulus for bulb-pressing. It proved effective, but the subject did not know why he responded. He said, "I just pressed" or "For some reason I felt like pressing." Faddeeva used a compound conditioned stimulus consisting of a bright red light coupled with a faint hooter sound. Subsequently, when the light was presented alone, the subjects (8- to 10-year-old children) always responded to it and reported its presence correctly. When the sound was presented alone, the subjects generally performed the motor response, but some reported having heard it, some did not, and some reported its presence but showed no

awareness of the connection between it and their motor response.

In general, according to Ivanov-Smolenski's summary, the occurrence of the stimulus, the occurrence of the response, or the connection between the two may or may not be reported. Verbalization is likely to be deficient when the stimuli are weak or when the subjects are young children or adults suffering from various neuropsychiatric disorders.

The development of verbal mediation with increasing age is further illuminated by Paramanova (1956), who, although not an associate of Ivanov-Smolenski, used his motor-conditioning technique. When differential training was given, some subjects learned not to respond to the negative stimulus very rapidly, but others were slow. The quick learners were found at all ages, but most of them were found among the older subjects, aged 5 to 6 years. They invariably answered questions about the procedure correctly. When the experimenters ceased to say "Don't press!" after the appearance of the negative stimulus, one or two subjects asked "Should I press?" The implication is that the response was under the control of verbal mediators and, in some subjects, was held in check until a verbal sanction had been given. The slow subjects were mostly younger subjects, aged about 3. The amplitude of their response to the negative stimulus gradually waned, and the latency gradually increased, until the response dropped out altogether. Verbal report was defective. When the positive stimulus was made negative and vice versa, older (5- to 6-year-old) subjects changed their manner of responding immediately, but the reversal took some time with the younger subjects. When reinforcement (i.e., telling the children whether they were right or wrong) ceased, 3-year-olds lost the differentiation, pressing the bulb in response to both positive and negative stimuli for some time. After that, they remained inactive until the instructions of the adult experimenter were renewed. Four-year-olds had some success at maintaining a differential performance, but there was considerable instability. Some used verbal instead of motor responses, remarking on the presence of the stimulus that had usually been paired with the experimenter's utterance. Some responded correctly but gave themselves audible instructions. By

the fifth or sixth year, response to the positive stimulus and nonresponse to the negative stimulus persisted, although there was some tendency to error

These experiments, Paramanova concludes, illustrate the tendency for direct control of behavior by external stimuli to give way gradually to the mediating influence of verbal stimuli. At first, the child is susceptible to control by verbal responses of adults, but he gradually becomes capable of self-control through his own verbal behavior

Voluntary Behavior

There has been a strong tendency among psychologists interested in learning to identify voluntary behavior with instrumental conditioned responses. Skinner (1938, p. 112) says that "The operant field corresponds closely with what has traditionally been called 'voluntary' behavior." Similarly, Ivanov-Smolenski (1956) identifies "voluntary movements" with "conditioned-conditioned-reactions," his term for instrumental conditioned responses

Instrumental conditioned responses have three characteristics, each of which has been singled out at one time or another as the distinguishing mark of voluntary activity. First, they are generally responses involving the motor division of the somatic nervous system and the skeletal (or, as they have sometimes been called, "voluntary") muscles. However, Skinner (1938, p. 112) pointed out quite early that "the 'voluntary' control of some autonomic activities is well established." Recent experiments by Miller (1966), in which visceral responses performed by curarized animals were followed by reward, seem to have conclusively and affirmatively settled the formerly disputed question of whether such responses can be subjected to instrumental conditioning. Second, instrumental responses are strengthened by rewarding consequences and apparently (although there has been some debate over this) weakened by punishing consequences. Third, instrumental conditioned responses frequently occur "spontaneously," that is, without being evoked by a specific external stimulus. As Kupalov (1964, p. 116), a leading Russian investigator of learned locomotor behavior in freely moving dogs, has put it, "those reactions are called voluntary that

are actively performed by animals and do not represent a response to a definite, special stimulus"

Some writers, mindful of the age-old inclusion of volition among the "higher mental functions," have felt that, to qualify as "voluntary," an action should not only be relatively independent of external stimulation but prompted by internal symbolic processes. James (1890) connected will with "ideomotor action," the process by which the idea of a movement leads to its realization, although he recognized that this would happen "unhesitatingly and immediately" only in "the absence of any conflicting notion in the mind." When there is "an antagonistic representation present simultaneously in the mind," he says, a "voluntary fiat" is needed to overcome it. Ach (1905, 1910) related will to the "determining tendencies" that, according to the introspective experiments of the Wundt school, could be set up by an experimenter's instructions. Analogous determining tendencies could be set up by an intention or decision of the subject himself.

The approach, and even the aims, of these early psychologists were, of course, very different from those of contemporary behavior theorists. Nevertheless, a behaviorist equivalent of their emphasis on the control of behavior by ideational acts and self-instructions was the view that a voluntary response is one that a subject can bring on at any time with the help of subvocal speech. In a celebrated experiment by Hudgins (1933), human subjects were first taught by a classical-conditioning technique to construct their pupils to a light-bell combination. The response was then conditioned to the word "Contract!" uttered by the experimenter while the subject produced the light-bell combination by squeezing a dynamometer, then to the verbal command alone, then to the subject's own pronunciation of the word "Contract!", and finally to the thought of the word. Other words, and even nonsense syllables, were used successfully in the same manner. Several later experimenters have brought other normally involuntary responses under the control of self-administered verbal stimuli by analogous techniques. Professional actors often bring on tears and other forms of emotional expression with the help of thoughts or postural adjustments that supply the neces-

sary conditioned stimuli Skinner (1938, pp 112-114) lists, in fact, four ways in which a human being can induce specific autonomic reactions in himself "at will" he can use unconditioned exteroceptive stimuli, unconditioned proprioceptive stimuli, conditioned exteroceptive stimuli, and conditioned proprioceptive stimuli

Nevertheless, although these procedures enable the subject to produce the responses in question "at any time" and are clearly a step toward voluntary control, it is possible to feel that voluntary control means more than the possibility of producing a response through internal verbal stimuli Hilgard and Marquis (1940) refer to the products of Hudgins's technique as "semi-voluntary conditioned responses" Naturally occurring human voluntary responses have additional characteristics They can be withheld when judged undesirable and they can be modified or interrupted while in process, if changes in the external stimulus situation warrant it

Such a restricted, but still objective, conception of voluntary activity appears in Zaporozhets's (1958, 1960) account He contrasts animals with plants, which have to rely on passive adaptation Animals "carry out an active search for the sources of satisfaction of their vital needs" In higher animals, the search depends on the skeletal musculature, but its use introduces many possibilities of error, because of the large number of degrees of freedom open to muscular responses, because of variations in the effects of bodily movements in accordance with the initial states of the muscles, and because of the many random factors to which muscles are subject For this reason, "sensory correction" is indispensable The organism has to be sensitive to signals indicating ways in which an action must be modified

Primitive animals can make use only of feedback that follows the completion of an action and tells whether or not the consequences are satisfactory This information about consequences can lead to a repetition of the action with modifications or to trial-and-error learning Human beings, however, are able to monitor the external situation and their own actions through feedback signals received while these actions are in progress Consequently, the actions can be corrected between their initiation and their conclusion,

which will maximize the probability that the consequences will be satisfactory To accomplish this, the subject needs to be guided by images of the external situation, of the consequences that an action is likely to have, and of the form a behavior chain should take As we have already seen, Zaporozhets sees a vital role for orienting (exploratory, attentional) responses, leading from one crucial stimulus to another, in the formation of the appropriate images He also acknowledges the importance of verbal habits belonging to the "second signal system"

Zaporozhets, assimilating ideas from several Russian authors, traces a course of development from excitomotor reactions (which depend on "irritability" and are evoked by simple stimuli) through sensorimotor reactions (which depend on "sensitivity" and are guided by orienting responses and thus by images), to voluntary reactions (which result from sensitivity to interoceptive and proprioceptive stimuli) Russian physiologists and psychologists have, since Pavlov (1932), always seen a close connection between "motor conditioned reflexes" (the term by which they usually refer to instrumental conditioned responses) and kinesthetic stimuli Zaporozhets relates this course of development to the appearance of vertebrate animals, which surpass invertebrates in complicated motor and neural equipment, and with the movement of higher vertebrates from aquatic to terrestrial environments, where vital objects are commonly surrounded by other objects that can serve as either means or impediments to their attainment

Zaporozhets's view, with its emphasis on feedback signals and orienting responses, receives support from an experiment conducted by one of his associates, Lisina (1958) She established voluntary control over a normally involuntary reaction in a very different manner from Hudgins and apparently more completely The response in question was vasodilatation in the hand in response to electric shock (running counter to the normal vasoconstrictive response), and her techniques worked by enabling subjects to recognize the extent and direction of their own vasomotor responses Some success was achieved when an auditory signal (a tone varying in pitch) or a visual signal (fluctuations of a recording pen) corresponded to vasodilation

and vasoconstriction. But the most successful procedure consisted of training subjects to recognize the faint and normally undetected proprioceptive sensations that result from vasomotor responses.

Luria's Experiments

Luria has traced the development of voluntary behavior by studying effects of verbal instructions. He distinguishes various functions that words uttered by an experimenter can have. The presumption is that subvocal responses of the subject himself, by which he influences his own actions, can perform these functions also. They comprise an *orienting* function, an *inhibitory* function, an *impelling* (or *initiating*) function, and a genuine *regulatory* (including *preselecting*) function. These functions are established in turn.

The beginnings can be discerned (Luria, 1959, Luria and Poliakova, 1959) when an infant surrounded by toys is given some instruction such as "Give me the fish!" Shortly after the first six months of life, the child will simply look up at the experimenter. At 10 to 12 months, he will look at the fish. Even up to 1½ years, the instruction is unlikely to interrupt activities in which the child is immersed. If not otherwise occupied, he may well respond, early in his second year, to "Give me the fish!" by handing the experimenter the fish. This, however, will occur only if the fish happens to be prominent in the visual field. That a true regulatory function of language has not yet been achieved can be seen from the fact that, if the fish is some distance away and there is a brightly colored toy cat close by, the child will look at the fish but give the experimenter the cat. The instruction is not reliably carried out until about the middle of the second year. One especially noteworthy characteristic of behavior during the second year is its perseveration. If a child between 1 and 1½ years is asked to hand over the fish three or four times in a row, he will still hand over the fish when the instruction is changed to "Give me the horse!" If a 1½- or 1¾-year-old child has just been putting rings on a stick and is told "Take off a ring!" while he is holding a ring in his hand, he is likely to respond by putting the ring on.

Another technique (Luria and Rozanova, 1959) consists of placing a coin under either

a cup or a tumbler out of the child's sight and then telling him "Now the coin is beneath the cup. Find the coin!" From 1½ to 1¾, the child looks fleetingly at the object that has been mentioned. On hearing the word "Now," he may seize both objects or turn to one of them, remaining unaffected by the name of the correct object when it is given. By the middle of the third year, the instruction will be followed correctly, unless a delay of 10 seconds is imposed before the objects can be touched. The delayed reaction is fully mastered by the end of the third year.

Here we have the beginnings of the delayed effects of verbal instruction. Their later development has been traced by Luria's group (Luria, 1956, 1958, 1961) with the help of a simple technique. The child is presented with a rubber bulb and receives some instruction such as "When the light comes on, press the bulb!" Between about 1½ and 2½, the child looks at the light on hearing the word "light" and starts pressing as soon as he hears the word "Press." There is no synthesis between the two clauses of the instruction and no storage of set or motivational condition such that the response is inhibited until the appropriate external stimulus appears. At this age, the child is, in fact, likely to continue to press until the light appears and then to stop in consequence of external inhibitions.

If, while he is pressing, he is told "That's enough!", this is unlikely to stop him but may, on the contrary, intensify the activity. If the admonition "Don't press!" is repeated, the result may be "complete irradiated inhibition and the discontinuance of all motor reactions." So we can see that the impelling function of verbal stimuli is uppermost at this stage. The inhibitory function is weak and nonselective.

By age 3½, the child will react appropriately to the instruction, pressing the bulb only when the light comes on. But inadequacies will become manifest when the task is made a little more complicated. If he is told "Press when a red light comes on but not when a green light comes on!", he will press in response to either light or to neither. If he is told "Press twice when the light comes on!", he is apt to press three or more

times All these deficiencies are overcome completely only at the age of 5 to 6 years

Further insight into the factors at work has come from various training procedures with which Luria and his associates (Iakovleva, 1958, Tikhomirov, 1958) have tried to remedy the shortcomings that appear at various ages For example, the child is taught to say "Go!" to himself when the signal light appears Up to 2½, this does not work, the child either soon gives up saying "Go!" or finds himself unable to say the word and press simultaneously because of inhibition by negative induction The device works much better in the third year and helps to reduce the intersignal responses to which children of this age are prone Between 4 and 4½, the child can improve his powers of differentiation (pressing in response to one color but not another) if taught to say "I must!" or "I must not!" appropriately when the signal appears Even at 2 to 3 years, performance is improved by providing "sanctioning afferentation," that is, an external stimulus (e.g., the sound of a bell or the sight of the light going off), when the motor response is performed correctly Two-year-old children can become capable of withholding the pressing response between appearances of the light if they are taught to move the hand away from the bulb as soon as each movement has been completed and not to return it until the next signal is seen

A 3- or 4-year-old child can be induced to press twice, and twice only, when the light is turned on, by training him to say "Go! Go!" on seeing the light The true nature of this phenomenon is, however, revealed when he is told to say "I shall press twice!" instead He then produces a single protracted movement instead of the two presses that are required It can thus be seen that the two syllables "Go! Go!" produce two presses through their impelling function The genuine regulatory function, involving response to the meaning of a verbal utterance, has not yet been perfected

Zaporozhets's Experiments

The copious experimental material gathered by Zaporozhets (1960) and his group takes over where Luria's investigations leave off They have carried the inquiry to the end of the preschool period (which in the Soviet

Union lasts until the age of 7) and have concentrated on complex tasks in which sequences of motor responses have to be made to sequences of external stimuli and in which there is room for planning

Great importance is attached to preparatory and orienting responses, which precede the executive responses that act on the external environment Orienting responses bring behavior under the control of essential cues and enable images to be formed of simultaneous or successive patterns of external stimuli before they are encountered Considerable emphasis is also placed on the development of the ability to imagine required bodily movements For example, when a child of 3 to 4 years is asked to show how he would use a comb or a pair of scissors, he drags his fingers through his hair or performs movements with his forefinger and middle finger From about 4 years on, he will place his hand in the posture it would have if he were actually manipulating a comb or a pair of scissors

The tasks employed in experiments by Zaporozhets and his associates include learning to discriminate visual figures, to trace a path through a maze, to perform gymnastic exercises, and to press buttons in coordination with visual signals The results show how spontaneous movements become more prominent, more efficient, and thus more capable of facilitating completion of the task, as the child grows older Various procedures for inducing orienting responses and making them more effective have had notable success

Other training procedures compare the efficacy of passive movement, demonstration of the correct behavior by the experimenter, and verbal instructions Passive movement is generally more helpful with younger children, and imitation with older children The relative merits of demonstration and verbal instruction depend on the complexity of the task and the nature of the cues on which its performance depends Verbal instruction is more effective when the required bodily movements are relatively simple and when external stimuli are of particular importance (e.g., in button-pressing tasks) Demonstration and imitation work better when proprioceptive stimuli are more important and when the required movements are complex (e.g., in gymnastic

exercises) One of the chief functions of verbal instructions is to draw attention to relevant cues in the external world. Relevant kinesthetic cues are brought to a child's attention most readily when he executes a pattern of movements that he has just witnessed.

The culmination of the development of voluntary movements and the link with thought processes become evident when internalization takes place. Inner speech comes to take the place of the audible speech through which verbal instructions are conveyed by adults. Conditioned orienting responses come to represent external stimuli in their absence. For example, a verbal instruction referring to a signal that is not yet present causes a child to look in the direction from which it can be expected. Ultimately, the progressive reduction of the orienting response with increasing age and with increasing mastery of a particular task leads to the formation of internalized equivalents of orienting responses, constituting imagery. As mastery proceeds, the executive response requires fewer and fewer preliminaries.

A particularly suggestive idea offered by Zaporozhets (see Beilyne, 1965a, Chap. 6) is that the processes through which we search for an idea or a solution when we think are internalized versions of the exploratory responses through which we search for concrete objects in the real world.

A recent addition to this series of investigations (Nepomniashchaya, 1965) considers the motivational side of volitional development. It starts out from Leont'ev's (1959) emphasis on a proper coordination between "motive" (the ultimate aim) and "goal" (a subsidiary goal that is a means to the ultimate aim). It shows how children below the age of 4½ will generally take up a task only if it is presented to them as a game to be carried out for its own sake (i.e., motive and goal coincide). They gradually develop the capacity to recognize actions as prerequisites for the later fulfillment of motives (e.g., making a toy, making a present to give to Mother). Anticipation of the ultimate consequences and recognition of the relation between the means and the end will then ensure enough motivation for the task to be taken up. We can thus see a progressive unfolding of the functions on which preparation and planning depend. Symbolic representation of events

that have not yet taken place and of the relations between components of the unified sequence is, of course, an essential ingredient.

CHILDREN'S REASONING ✓

Although much human reasoning does not lead immediately, or at all, to overt action, reasoning is biologically important as a means of arriving at an adaptive response pattern, which generally means a response pattern that will be rewarded. Once the rewarding consequences have occurred, the response pattern will become more likely to be performed in the presence of pertinent stimulus conditions. So reasoning can be regarded as an adjunct to instrumental conditioning, an aid to the acquisition of learned behavior. In order to view reasoning in perspective, we must therefore compare it with other ways in which the first occurrence of an adaptive response pattern can come about.

Trial and Error. In accordance with Thorndike's (1898) description of "trial and error and accidental success," an organism can sample its behavior repertoire (with replacement) until a successful act turns up. The distribution on which the sampling is based will generally vary with the stimulus situation, since experienced members of higher animal species will be most likely, in the course of trial and error, to do things resembling what has worked in similar situations in the past. An experimenter relying on this process is compelled simply to wait until the selected response occurs spontaneously. If the response is a simple one, with a relatively high operant level, such as bar-pressing or panel-pecking in a Skinner box, he will not have to wait long. But if it is a complex combination or succession of acts, or a response with a low initial probability, trial and error alone cannot be expected to produce it at all.

Successive Approximation. An experimenter can speed up the emergence of a relatively improbable response pattern by requiring successively closer and closer approximations to it before delivering reward (*shaping*). Either an experimenter or nature alone can gradually steer an organism toward a behavior pattern by rewarding remote

semblances of the optimal behavior to a slight degree and rewarding closer and closer approximation more and more intensely (*cybernetic search*)

Evocation. A stimulus can be administered that is known to evoke the adaptive response pattern. For example, Biogden (1939) used a tone that had been paired with electric shock to evoke leg retraction in the dog, and Konorski (1967) induced ear-scratching in the cat by placing cotton in the ear. In both experiments the response, once it had occurred, was reinforced with food. There are three special cases of this kind of technique that warrant particular notice. In *passive movement* a specific bodily movement is brought about by mechanical force. This technique was used in the original instrumental-conditioning experiments of Miller and Konorski (1928), who used a cable-and-pulley arrangement to make dogs flex their paws. Similarly, trainers of circus and domestic animals commonly push their pupils into the desired postures, and human beings may be taught skilled movements by having their limbs held and guided. The second special case is *imitation*, also known as *modeling* (Zaporozhets, 1960, Bandura and Walters, 1963). Here the stimuli that evoke the desired responses are the visual or auditory cues that come from another individual who is deliberately or inadvertently demonstrating the response. Finally, a response pattern can be evoked in human subjects by *verbal instruction*.

Deferred imitation. A human being can witness a response without at the time performing it himself and become in consequence likely to do the same on some future occasion. When this deferred imitation (Piaget, 1945) leads to a learned strengthening of the response, *observational learning* is said to occur. When learning depends on witnessing not only the act but also the consequences of the act for the individual performing it, the term *vicarious learning* is used (Bandura and Walters, 1963, Bandura, 1965).

Deferred Response to Verbal Instruction. A human subject may hear or read a verbal description of a course of action and, although he does not put the instruction into practice immediately, it may cause him to perform the described behavior in appropriate circumstances at a later time.

We can thus comprehend the problems raised by reasoning if we review the similarities and differences that relate it to these other processes. Reasoning clearly contrasts with trial and error by making it possible for adaptive behavior to emerge much more quickly and, more often than not, by bringing about forms of adaptive behavior that trial and error could never have generated at all. Like response to verbal instruction, reasoning depends on ability to respond appropriately to verbal stimulus patterns. But as with deferred imitation and deferred response to instruction, there must be response to internal representational structures that have been deposited during earlier learning experiences and are now revived after what may well be a considerable delay. However, the internal symbolic patterns that underlie deferred imitation and response to instruction need to be relatively faithful copies (imaginal or verbal) of those induced by the demonstration or the verbal description at the time of the original learning. The symbolic patterns that result from reasoning are, in contrast, unlike any that the subject has had at his disposal before, they have to be constructed out of elements belonging to several previous learning experiences. Lastly, we must note that imitation and verbal instruction (whether or not response to them is deferred), as well as passive movement and shaping, require the intervention of another organism. According to the definition offered by Mowrer (1950, p. 675), following a suggestion made by one of his students, they are all examples of *teaching*. Reasoning, on the other hand, is something to which an individual can resort on his own. The learning experiences on which a specific piece or reasoning builds may or may not have been induced by teaching. The presence of a teacher, who is eager to provide hints and feedback, may well assist reasoning while it is going on. But reasoning can proceed without external supports and is alone in this respect among the various short-cuts to adaptive behavior that make use of symbolic capacities.

Piaget

The development of inferential thinking has received its most ambitious theoretical analysis from Piaget. His is also the most

thoroughgoing attempt that has been made so far to chart its course empirically

Piaget traces the roots of logic back to the sensorimotor stage, which embraces the first two years of life when external stimuli evoke responses with little or no intervention of symbolic mediators. During this stage, the child learns to "coordinate schemata." This means both piecing together stimulus-response associations into sequences through which goals can be attained and recognizing two or more sequences as alternative, and therefore equivalent, ways of arriving at the same terminus from the same starting point. It is significant that these correspond to the two properties defining Hull's "habit-family hierarchies" (Berlyne, 1965), namely, the formation of "behavior chains" and the recognition of equivalence between behavior chains that lead to the same goal-situation from a common initial stimulus situation.

The ability to make use of systems of "co-ordinated" elements is later transferred from the level of motor actions to the level of internalized actions, which include symbols. In manipulating symbols, the child takes some time to relearn some of the lessons that he has already mastered while manipulating sensorimotor schemata. By the end of the sensorimotor stage, the child becomes capable of the simple forms of adaptive behavior that do not require human symbolic capacities. He becomes capable, for example, of the kinds of reasoning or "insightful" problem solving that Kohler (1921) and later experimenters observed in apes. He will use a stick to obtain an object that is otherwise out of reach. He will also perform actions that are prerequisites for later actions, for example, rotating a stick so that it can pass between the bars of a playpen, walking to the far end of a doll carriage in order to push it away from a wall. All of these solutions are discovered without overt trial and error.

Directed thinking appears once behavior has come under the influence of language, images, and other internal symbols, but thought processes are for some years subject to serious limitations. During the *preconceptual stage* (2 to 4 years), the child depends heavily on "transduction." This term, which Piaget has taken over from Stern (1914), denotes reasoning from the particular to the particular, it infers that, because one object or event has

a certain characteristic, a similar object or event will also have it. General statements, which are essential to induction and deduction, become important during the *intuitive stage* (4 to 7 years), but conclusions are likely to be erroneous. This is due to an imperfect understanding of class-membership and class-inclusion (Piaget and Inhelder, 1959). Reasoning is also impeded at this stage by an undue dependence on perceptual data, coupled with a tendency to attend to one aspect of a stimulus situation while overlooking other, equally significant aspects (Piaget, 1945).

The stage of *concrete operations* (7 to 11 years) introduces the use of operations. Operations are organized in groupings (*groupements*). These approach the properties defining algebraic groups without quite fulfilling them (Piaget, 1941, 1947). With their help, the child is able to make correct inferences belonging to the algebra of classes, the algebra of relations, and elementary arithmetic.

Finally, the stage of *formal operations* (Inhelder and Piaget, 1955) coincides with early adolescence (11 to 15 years). Deductions identifiable with the propositional calculus are mastered. Implications can be derived from the relations between propositions, regardless of concrete content. Consequently, hypothetico-deductive reasoning, that is, the ability to state what *would* follow *if* something were the case (when it is not), becomes possible. So does reasoning that requires understanding of ratios and probabilities.

Inhelder and Piaget have analyzed this stage with the help of ingenious experiments in which the adolescent subject is confronted with phenomena illustrating simple physical and chemical principles and asked to work out the laws governing these phenomena. During the stage of formal operations, he first becomes capable of devising conclusive experiments by conceiving of, and then examining, all the possible combinations of events that could occur. In attempting to explain the kinds of reasoning that first appear during this stage, Inhelder and Piaget refer copiously to the "four group," a group of four transformations, each of which has two opposites, an "inverse" and a "reciprocal." They also make much of a system of relations between logical connectives, analogous to proportional relations between numbers, that Piaget has discovered. Commentators (e.g., Parsons 1960, Berlyne, 1965), while

acknowledging the crucial role of algebraic groups in logical, mathematical, and scientific thinking, have questioned the suggestion that the adolescent actually makes use of these logical "proportions" or that the four group has the unique role that Piaget attributes to it

Experiments Inspired by Piaget

The experiments that have been inspired by Piaget's writings but carried out in other laboratories have some way to go before they outstrip in number those carried out in Geneva, but they are catching up. Much of this work has been aimed at verifying Piaget's statements about the development of concepts or "notions" and is thus not directly relevant to our present discussion. Lately, however, there has been a growing body of work on quantitative invariants like quantity, number, and weight, which began to be understood at about the age of 7. As argued elsewhere (Berlyne, 1965), the recognition that, say, quantity remains constant when a shape or spatial distribution changes must depend on deduction from stored information. This makes it a better paradigm for directed thinking, especially directed thinking about dynamic processes, than that old standby, the concept-formation experiment. Nevertheless, work on the origins of such judgments and on ways of accelerating their appearance is treated elsewhere in this *Manual* and has, in any case, been lucidly reviewed by Wallach (in press).

Braine (1959) has investigated inference from transitive relations ($A > B$, $B > C$, $A > C$), using a nonverbal length-discrimination task. This is a step toward bridging the gap between Piaget's use of verbal responses to study reasoning and the experimental techniques of behavior theory. It was concluded that such inferences, which according to Piaget should not generally occur before the age of 7, actually occur two years earlier.

The publication of Braine's monograph touched off a controversy with Smedslund (1963). He has criticized Braine's technique, asserting on a number of grounds that he failed to demonstrate that correct responses must have resulted from inference. He also claims, with support from experiments of his own, that transitivity of length is not generally recognized before the age of 8. Smedslund (1961, 1963) also attaches importance to the

explanations that children give of their judgments. He maintains that, say, conservation of a property like weight or length can be said to have been "acquired" only when subjects defend their conclusions deductively, mentioning both of the premises from which the conclusion must be inferred. Nonverbal discrimination alone does not demonstrate that this stage has been attained.

Halpern (1965) has shown that a child's verbal explanations can be indicative of the progress he has made in moving from the reliance on perceptual cues that characterizes the intuitive stage to the predominance of thought processes that comes with the stage of concrete operations. She took children who, when confronted with three objects of equal size, acknowledged that, if A weighs more than B and B more than C , A must weigh more than C , and who could also recognize that weight must remain unchanged when the shape of a ball of plasticine is altered. She then divided these children into two groups, according to whether their explanations of conservation of weight had been "empirical" (i.e., they directly or indirectly referred to observable features of the stimulus situation now confronting them) or "deductive" (i.e., they directly or indirectly referred to previous events, such as having seen objects weighed in the same test item). The empirically oriented children made more errors when tested for transitivity of weight with objects of differing sizes, especially when size was negatively correlated with weight. When these children were asked to compare A and C for weight, the influence of a demonstration on a balance that A weighs more than B and B more than C was unable to outweigh the influence of perceiving C to be larger than B .

More and more experimenters have been examining the changeover between concrete and formal operations. Lovell (1961) has repeated many of Inhelder and Piaget's experimental procedures and, with the exception of a few specific points, has come to the same general conclusions as they. Lunzei (1965) obtained relatively few successful solutions for children below the age of 10 or 11, when he set verbal problems depending on structures of a form A is to B as C is to D . This finding, he contends, is compatible with the argument that such problems, even if concrete in content, require formal operations, since the sub-

ject must recognize relations between relations Nassefat (1963) gave 9- to 13-year-old subjects about 50 problems, which he divided into "concrete," "intermediate," and "formal," according to the kinds of thinking that they required. As expected, when performance was related to age, the concrete problems were the first, and the formal problems the last, to evoke a predominance of correct solutions. Likewise, there tended to be a progression with increasing age from answers showing "absence of correct perception of the data of the problem," to "insufficient perception of the data" then to "insufficient combination of the data," and finally to "correct perception and combination of data."

Case and Collinson (1962) questioned 11- to 18-year-old subjects about texts that they had read and gave 1, 2, or 3 points to each answer according to whether it manifested intuitive thinking, concrete operations, or formal operations, respectively. The score obtained by a summing of these points was positively correlated with chronological and mental age. But the mean was found to move by "blocks of ages" rather than increasing gradually with age. There was a significant difference between 15- to 17-year-old and 11- to 12-year-old subjects. Cowan (1963) gave 8- to 13-year-old subjects "concrete" problems (requiring them to compare A and C for weight after being told A weighs more than B and B weighs more than C) and "formal" problems (resembling the "concrete" problems except that relations between objects were denoted by nonsense syllables). There was a moderate positive correlation between overall performance and mental age, and there was some evidence that concrete reasoning is mastered earlier than formal reasoning. There was, however, no support for the assumption that "concrete or formal operations emerge suddenly at any given age level."

Other experimenters have looked for signs at much earlier ages of the kinds of reasoning associated with the stage of formal operations. Mogai (1960) gave demonstrations to children from kindergarten and second and fourth grade classes of phenomena having to do with floating and nonfloating bodies and with the projection of shadows. Adequate explanations of this phenomenon became commoner with increasing age within this range. Ervin (1960) took another of the problems used by Inhelder

and Piaget (1953). Second- and third-grade children were set the task of discovering the principles that govern the flexibility of a rod. A few children in each age group discovered all four operative variables (length, material, thickness, and form of cross section). Failures resulted from tendencies to repeat unsuccessful predictions, to focus on an unduly narrow range of hypotheses, to be confused over terminology, and especially to overlook uncontrolled variables.

McLaughlin (1963) has offered an alternative to Inhelder and Piaget's interpretation of the obstacles that have to be overcome before immature forms of thinking can be replaced. He holds that limitations of immediate memory or of attention can account for the belated appearance of more advanced thought processes, arguing that pre-operational, concrete-operational, and formal-operational thinking require, respectively, two, four, and eight concepts to be handled simultaneously.

5- The Influence of Kohler: Insight versus Trial and Error

Phenomena demonstrated in animals have served as reference points for investigators of reasoning in children. Kohler's (1921) experiments on "insightful" problem-solving in the chimpanzee have been a particularly fruitful source of experimental techniques and theoretical issues. The foremost question raised by Kohler was the relative importance of, on the one hand, the discovery of successful responses by trial and error and, on the other hand, sudden perceptual restructuring and understanding of relations between the elements of the problem situation. It has, however, become more and more evident that this is not a sharp dichotomy (see Berlyne, 1965). This "blindest" so-called "random" trial-and-error behavior is never a random sample of the responses of which the organism is capable but rather a selection of acts that have proved useful in somewhat similar situations in the past. And both American and Russian experiments (the latter carried out under Pavlov's supervision toward the end of his life) have shown how "insight" depends on prior acquisition through learning of the essential ingredients of the solution.

Piaget's reports of behavior in infants resembling that of Kohler's apes have already been mentioned. Historically, the first such

observations seem to have been made by Buhler (1930). One infant whom he studied was able by the end of the tenth month to pull on a string and thus obtain a cookie that was attached to it. The ability to remove a ring from a post by lifting it rather than trying to pull it sideways did not, however, appear until the middle of the second year.

Two American experimenters, Alpert (1928) and Matheson (1931), have exposed pre-school children to situations resembling those that confronted Kohler's chimpanzees. They were required to obtain otherwise inaccessible objects by means of sticks or strings, to move a block to a position where they could stand on it to reach something hanging from the ceiling, and so on. The commonest reaction observed by Alpert was "explosion and elimination," that is, "a deliberate giving out of one possibility after another or an investigation of the constituent parts of the situation." It was sometimes "guided by a partial understanding of or insight into the situation." The next most frequent was the "preparatory response," that is, reaching out with the hand. This usually occurred when the child was first placed in the situation, but it was apt to recur after failing to solve the problem. The "random response," comparable to the trial-and-error behavior of Thorndike's cats in the puzzle box, appeared generally as part of an emotional reaction to being thwarted. The "immediate solution," possibly preceded briefly by a preparatory response, occurred relatively rarely. Nevertheless, it appears that any type of response will lead to a solution "only if the subject has gained insight into the problem-situation." According to Matheson's records, "manipulation" and "pointing and reaching" (identifiable with trial-and-error) were most frequent, followed by "feelings of incapacity" and "asking the experimenter to help him." Like Alpert, Matheson states that "solutions which occurred without preliminary manipulation" were relatively rare. She equates them with Kohler's insight, which seems to be an example of a surprisingly widespread misconception. Reference to Kohler's protocols will make it clear that what he calls "insight" does not preclude prior trial and error. The general conclusion that "understanding may occur in differing degrees" seems well taken and agrees with comments made by other investigators of reasoning. Both Alpert and

Matheson found positive and moderate correlations between success at these tasks and chronological and mental age.

Richardson (1932, 1934) tested infants monthly between the ages of 6 months and 1 year for ability to obtain lures by pulling strings or turning levers. With increasing age, there was more and more of a tendency to pay attention to the strings or levers. The author concludes that "perceptive attitudes" and motor capacities develop hand in hand and that both of them contribute to the development of proficiency at tasks of this kind.

Some more original tasks were devised by Harter (1930). They all required the subject to find a way of removing or circumventing obstacles, so that an object could be transferred from one location to another. The salient observation was of "considerable overt trial and error." There was also evidence for some learning, since subjects made fewer random moves when faced with a specific task for the second time, but one-trial learning often taken as another criterion of insight, was not in evidence.

Russian Work Transfer from Previous Learning

Beginning with Pavlov, Russian representatives of psychology and "physiology of higher nervous activity" have been unable to ignore Kohler's chimpanzee experiments. However, like many of their Western colleagues and for strikingly similar reasons, they have taken exception to Kohler's theoretical interpretation with its emphasis on "insight" as something that cannot be reduced to learning. They have felt challenged to show that the same phenomena can be explained by a suitable extension of Pavlovian conditioned-reflex principles.)

Some pertinent experiments with children, paralleling the experiments with chimpanzees that were going on at about the same time under Pavlov's direction, were carried out in Ivanov-Smolenski's laboratory and reported in a book edited by him (Ivanov-Smolenski, 1934). As in the experiments by the same group that were mentioned earlier, the favorite response of pressing the rubber ball with the hand was generally used. No verbal instructions were generally given, except for utterances like "Press!" and "Don't press!" when these were selected as unconditioned

stimuli. Furthermore, the subject was alone in an experimental chamber. In these conditions it is easier than it is in most human experiments to compare the behavior that emerges with animal behavior and with simple forms of conditioning, even though this behavior must be influenced by thought processes and by attempts to figure out what one is supposed to do. II

Naroditskaia studied "The formation in childhood of new conditioned connections without previous elaboration." In an initial phase, children were taught, with a verbal unconditioned stimulus, to press a rubber bulb in response to either a red square or the sound of a bell. The response was followed by either the receipt of a piece of candy or the appearance of a picture. In a second phase, the conditioned stimulus was changed: the red square was replaced by a yellow rectangle or the bell by a tone. In a third phase, the original conditioned stimulus was used, but the response was changed by introducing either a bulb of a different shape or the same bulb in a different location. In a fourth phase, both stimulus and response were changed. These last three situations can be recognized as calling for Hull's (1943) "stimulus generalization," "response generalization," and "stimulus-response generalization," respectively. The crucial role of the last of these in reasoning has been elaborated on elsewhere (Berlyn, 1965a, Chap. 7). Naroditskaia found the percentage of subjects acting appropriately in all three transfer tasks to be 28 at preschool ages, 40 in 7-to 8-year-olds, and 80 in 10-to 12-year-olds. III

In Khozak's experiment, entitled "The formation of conditioned connections in the child by means of a cross-over on the basis of past experience," children were first confronted with a grey, pear-shaped bulb and the sound of a bell. They did not press the bulb. They were then taught to press a flat brown bulb in response to a flashing green light and to press a button in response to a rattling sound. Candy was given as a reward in both cases. After these two training experiences, they were presented with the initial situation. The majority of the children then pressed the pear-shaped bulb. Once again, we see an instance of stimulus-response generalization, although the factors at work are not altogether clear. Some children did not press the

bulb in the final stage but, when asked what they should be doing, they nevertheless answered "Press!" This might mean that the required association could be generated by a verbal mediator, elicited by the question, but would not appear without it. But it might mean instead that these children recognized the action that was appropriate but were prevented by some kind of timidity or scruple from performing it.

In an experiment on "The neurodynamics of suddenly arising conditioned closures in complex situations," Kothiaevski introduced an additional feature of Kohler's ape experiment, the necessity of a preparatory tool-using response before the directly reinforced response can occur. Children were taught to press the bulb, as a means of obtaining candy, on seeing a flashing yellow square. The response was, however, not reinforced when the square was accompanied by the sound of a bell. Later, they could reach the bulb only after loosening the tube to which it was attached and unwinding it from a hook or else by fitting two sticks together to form an instrument by which it could be pulled toward them. These supplementary actions were frequently evoked by the positive conditioned stimulus, the flashing yellow square. But inhibition generalized to the new situation when the square and bell were presented together. Both trial and error and sudden insight were observed. Like Naroditskaia, Kothiaevski found the frequency of success to increase with age between 5 and 12 years. IV

An active team headed by Rubinshtein (1958, 1959, 1960) has focused on another aspect of transfer from previous learning. They view thinking as an interplay of "analysis" and "synthesis." Pavlov used these terms to denote, respectively, the processes by which properties of stimuli are distinguished and registered (the work of the "analyzers," i.e., the sensory nerves and sensory areas of the brain) and the evocation of responses through "conditioned connections" or (in the case of verbal events) "associations." Rubinshtein extends these notions considerably. Under analysis, he includes taking cognizance of the data of a problem, picking out essential components, considering its different aspects. Analysis of sensory images is distinguished from analysis of verbal "images," which is

essential to human thinking. There is "analogous filtering," which means simply focusing on one facet of a problem after another. But special importance is attributed to "analysis through synthesis." This occurs when elements of the problem are related to one another and especially when the requirements of the solution and the conditions within which the solution must be reached are considered jointly. In its turn, a new analysis or "formulation" of the problem leads to new "synthesis" by bringing new thoughts into play. This happens, for example, when relations emerge between the present problem and other problems to which solutions have been found in the past.

Some of the experiments illustrating these points have been done with children. For example, in an experiment by Zhukova (1960), children between 3 and 6 years of age had to select an instrument with which to extract a piece of candy from a container. One group was presented with hooks of different shapes and colors, while a second group had hooks of different shapes but of the same color. At first, no subject could solve the problem without trying out different hooks in turn, but, after a while, they could pick out a hook of the right shape without trial and error. This transition to "the plane of cognition" required about half as many trials in the second group as in the first group. It is suggested that the conditions used for the first group are representative of the conditions in which most everyday thinking goes on. The stimulus properties that could guide one to a solution are mixed up with other, irrelevant stimulus properties. The processes of structuring and generalization on which a "proper analysis" of the problem or discovery of its "functional meaning" depend are therefore impeded. The subjects of the second group were, in contrast, able to concentrate on the property that mattered, namely shape. In another experiment, Slavskaya (1960) presented children of 13 and over with geometrical problems, seeking the conditions in which supplementary questions, containing hints, could be useful. Subjects could, it turned out, take advantage of a supplementary problem only when analysis of the main problem had gone far enough for the relation between the two to be recognized.

Reasoning in preschool children has been one of the concerns of the Moscow school, which carries on the tradition of Vygotski. Several experimenters have taken it up under the direction of Leont'ev and Zaporozhets (El'konin, 1960; Zaporozhets and El'konin, 1964). Once again, subjects have to gain access to objects with the help of intermediary instruments (which sometimes have first to be constructed or modified). And again, the findings are deemed to refute Kohler's view. Transfer from previous learning, especially learning that has resulted from social interaction, is seen as the key to what Kohler called "insight." To quote Zaporozhets (1960, p. 212), "At first, the child carries out a transfer solely on the basis of an external similarity between situations, but subsequently—even in preschool years—he begins to grasp internal mechanical connections in the relations between objects and, after solving a series of similar but simpler mechanical tasks, he grasps the principles that unite them and forms the corresponding generalizations."

Under the joint influence of Pavlov's emphasis on the central role of the second signal system in human behavior and Vygotski's emphasis on words as transmitters of social influence, these Russian investigators dwell on the importance of speech as a vehicle of generalization that ensures appropriate transfer from relevant previous experiences to the present problem. There are some close parallels between their views on this matter and the views of American psychologists (e.g., Miller and Dollard, 1941; Staats and Staats, 1963) on the functions of verbal mediators. Furthermore, the importance attached to exploratory ("orienting") activity and the links established between this activity and imagery have drawn attention to the way in which images, like words, make it possible to plan a solution to a practical task beforehand and thus obviate the need for overt trial and error.

However, the ability to use these symbolic aids takes time to develop. Minskaya (1954) set children various tasks requiring manipulation of levers. Three different conditions were compared. One group had to discover the solution while handling actual levers ("the visuo-operative level"). A second group had to describe how they would solve the problem, using a drawing of the equipment ("the visuo-imaginal level"). The third group

had to describe in words how the problem could be solved ("the verbal level") More than 50% of the children in the first group succeeded, even at 3 to 4 years This percentage was not reached until 4 to 5 years in the second group In the third group, there was only 22% success even at 6 to 7 years, the oldest age group tested Minskaia also examined the role of exploration ("orientation"), distinguishing four levels "primitive-chaotic," looking round the room, paying attention to the lure but not particularly to the lever through which the lure was to be secured, concentrating on the lever and manipulating it, conceiving of the solution after simply examining the components of the lever visually There were no successes at all with the first kind of exploration, but the percentage of success rose from the second to the fourth The fourth kind became commoner with increasing age

The importance of transfer from previous learning even for logical deduction is illustrated in an experiment by Ul'enkova (1954) The ability to make correct deductions from premises was almost absent at 3 to 4 years and gradually increased to 80% success at 7 years The probability of success varied both with the form of the underlying syllogism and with the content of the premises, depending on how close they were to the child's experience A training procedure, designed to "actualize" past experience and induce the formation of appropriate universal statements, had no effect on 3-year-olds, but improved ability to handle syllogisms in older children Its efficacy increased with age Four stages in the formation of deductive thinking were distinguished First, the child does not form any universal statements or generalizations, he does not give grounds for his assertions or, if he justifies them, he does so haphazardly Subsequently, the child operates with universal statements, but they are often invalid and they are, in any case, introduced inappropriately and haphazardly In a third stage, the child uses appropriate and valid universal statements but does not consider all possible cases Finally, the child overcomes all these deficiencies and can draw valid conclusions This investigation clearly deals with some of the same processes as Piaget's developmental studies of logical thinking It is a little hard to compare their

findings, since Ul'enkova's tests were based on the syllogisms of Aristotelian logic, whereas Inhelder and Piaget patterned their procedures after the inferential forms of modern symbolic logic Ul'enkova's data seem, however, to suggest that processes associated by Inhelder and Piaget with early adolescence can actually appear earlier

Maier and Hull Synthesis of Learned Associations

Maier (1936) reported an experiment on reasoning in children in which he pursued a conceptualization arising out of his earlier experiments with rats and with human adults He contrasted "reasoning" (the "ability to combine two isolated experiences") with "learning" (the "ability to combine two contiguous experiences") His rat experiments had led him to conclude that these two abilities are distinct, since (1) brain injuries that impair reasoning do not affect learning, (2) reasoning is better in older rats and learning in younger rats, and (3) tests of reasoning ability are highly correlated with one another but not with tests of learning

In the title of an article reinterpreting Maier's and Kohler's reasoning experiments, Hull (1935) spoke in the same vein of "The mechanism of the assembly of behavior segments in novel combinations suitable for problem solution" Related views have been expressed in the Soviet Union Vatsuro (1948), who studied tool-using behavior in chimpanzees under Pavlov's direction, concluded that qualitatively new "dynamic patterns of temporary connections" can result from the interaction of distinct previously acquired conditioned reflexes Boiko (1955, 1957) has described how new "temporary connections" can be formed "without preliminary elaboration" through the simultaneous evocation and interaction of two or more conditioned reflexes whose fields of cortical excitation overlap This kind of process, he maintained, underlies the "higher mental processes," including deductive and inductive thinking

In his experiment with children, Maier used an arrangement of enclosed alleys, shaped like a swastika, with a booth at the end of each arm The booth could be entered from inside or from outside the apparatus Following the procedure Maier had already

introduced in his rat experiments, the child was initially given two distinct learning experiences. First he was allowed to explore the interior of the apparatus, and, second, he was led into one of the booths from outside and shown a toy windmill whose arms would rotate to the accompaniment of a tune if a coin were dropped into a slot. In the test phase, the child was taken out of the apparatus and into another booth, from which he was to find his way to the booth containing the toy. Above-chance success, regarded as an index of reasoning, was "rarely developed to a marked extent in children below 6 years of age." Since children are able to learn much earlier than that, Maier felt confirmed in his belief that learning and reasoning correspond to distinct abilities. Success at his reasoning task was correlated with mental and chronological age.

In a series of experiments inspired by Hull's (1935, 1952) analyses of reasoning, the Kendlers and various collaborators have used the kind of apparatus depicted in Fig. 2. The child is first trained to perform three responses: response A leading him to subgoal B, response X leading him to subgoal Y, and manipulating subgoal B leading him to the major goal, G. He is then presented with A and X simultaneously to see whether he will choose to perform A, the response by which he could attain the main goal. For example, in the first experiment, response A was pulling a ribbon, which caused subgoal B, a toy ladybug, to appear. Response X was pulling a chain, which caused subgoal Y, a toy chicken, to appear. The major goal, G,

Fig. 2 Basic plan of apparatuses used in experiments on inference by Kendlers and associates (From Kendler, Pliskoff, and D'Amato, 1958)

was a toy car. In later experiments, different manipulanda and responses were used, but the general scheme was the same.

In the first experiment (Kendler and Kendler, 1956) there were eight groups of 3- and 4-year-old children. Four experimental groups had two trials with the A-B response, the X-Y response, and the B-G response, but the order differed from group to group. Four corresponding control groups underwent the same treatments except that the B-G response was not introduced; they were simply shown the main goal instead. In the subsequent test phase, the experimental groups performed the correct response (pulling A) significantly more often than the control groups. This contradicted Maier's conclusion that reasoning is not generally present before age 6. As far as the orders were concerned, there was evidence of inference when the A-B response was learned before the B-G response but not when the B-G response was learned first.

The details were modified in the second experiment (Kendler, Kendler, Pliskoff, and D'Amato, 1958). All subjects acquired the A-B response, the X-Y response, and the B-G response, in that order. The two independent variables of interest were "reinforcement during training" and "motivation during the test trial." Half of the subjects found a gold charm in the major-goal container and the other half did not. Furthermore, half of the subjects could see the major-goal container through a window during the test trial, and the other half could not. Subjects who received a charm during the training trials and also could see the major goal during the test trial performed better than subjects for whom one or both of these conditions were absent. "It was concluded that inferential behavior, like the simple bar-pressing habit in animals, is influenced by independent variations of reinforcement and motivational variables."

The third experiment (Kendler and Kendler, 1961) reverted to the question of whether the order of acquiring the components of the solution chain makes a difference. A third version of the apparatus was used. In the training phase, all six possible orders of acquiring the A-B, X-Y, and B-G responses were used for different experimental groups. The groups did not, however, differ significantly in incidence of inference. This finding failed to support explanations of inference

derived from writings of Hull (1935, 1952), Skinner (1938), and Underwood (1952) How reasoning may be explained without assuming that the contributing associations must be acquired in a particular order has been discussed elsewhere (Beilbyne, 1965a, Chap 12)

A fourth experiment (Kendler and Kendler, 1962) introduced various complications into the procedure The training phase was more elaborate, and the subgoals were interchanged for some subjects in the test phase, so that response *A* produced subgoal *Y* and response *X* produced subgoal *B* Children of 8 to 10 years were tested as well as kindergarten children A significant tendency to choose the correct response in the test phase was shown by the older children but not by the younger children The discrepancy between this finding and the success that had been obtained with younger children in the earlier experiments was attributed to the higher socioeconomic status of the earlier subjects and the additional complexity of the present task The behavior of the children for whom the correct response in the test phase produced the incorrect subgoal and vice versa showed that the formation of a solution chain is not determined solely by the presence of external stimulation from the appropriate subgoal but depends also on choice of the correct initial response

The most recent experiment in the series (Kendler, Kendler, and Carrick, 1966) concentrated on the influence of verbal labels Some subjects were taught to apply identical names to the subgoal object, *B*, that figured in the *A-B* association and to the *B* that figured in the *B-G* association Some were taught to apply different names to them Some were not led to apply any verbal labels to them at all during training The dissimilar labels had no consistent influence on the incidence of correct solutions The use of identical labels made correct solutions more frequent at the kindergarten level but either made no appreciable difference or had a detrimental effect in grade-3 children To account for these findings, the authors suggest that older children supply their own verbal labels and that the induced labels either coincide with these, thus adding nothing, or conflict with them, impairing performance

Investigations Arising Out of Educational Problems

Tests of reasoning ability have, of course, long been of interest to educational psychologists A considerable body of theoretical writing has grown up along with the testing movement, much of it relating to classification of intellectual abilities with the help of factor analysis and other taxonomic techniques (e.g., Spearman, 1927, Thurstone, 1938, Guilford, 1967) For a long time, there was a wide and highly regrettable chasm between those who were measuring intellectual capacities and those who were doing experiments to discover the laws that govern intellectual processes Fortunately, the educational reform movement of the 1960s has begun to bridge this gulf between applied and basic research

An interesting example of a synthesis between the two approaches is Donaldson's (1963) book She set children various problems such as are widely used in intelligence tests They included matching problems, three-term-series problems, series-extrapolation problems, related-series problems, and problems requiring formal deductive reasoning Her aim was to find out how errors arose, and her findings led her to place them in three major categories There were "structural" errors (due to "failure to appreciate the relationships involved in the problem or grasp some principle essential to the solution"), "arbitrary" errors (due to "a lack of loyalty to the given"), and "executive" errors (due to "some failure in the actual carrying out of the manipulations required") With reference to the last category, the author says that "some defect of concentration, of attention, or of immediate memory seems usually to lie at their origin"

The growing appreciation of creativity and independence of thought by contemporary society has encouraged educational psychologists to seek ways of promoting intellectual capacities rather than simply diagnosing them By delving further into the operative mechanisms than was customary until recently, an investigation like Donaldson's can contribute to this change Two studies supervised by Suppes (Suppes and Hill 1961, Suppes, 1966) were similarly prompted by hopes of advancing pedagogical technique Children ranging between 6 and 8 years

of age were set problems, each of which presented them with two or three premises and required them to state whether or not a particular proposition would follow

The percentage of correct answers increased from 71.18 at 6 years to 85.58 at 8 years. A control group, for whom the first premise of each item was omitted, answered correctly 52.02% of the time. The inclusion of negative propositions among the premises raised the probability of error.

The second study was concerned with the ability of first-grade children to construct proofs in a simple mathematical system. One training procedure used discrimination learning with correction. After arriving at each line of the proof, the subject had to choose from four alternatives the kind of step that needed to be taken next. He was then shown the correct choice. Children trained with this procedure made fewer errors than others who were trained with a discovery method and not corrected until the whole proof had been completed.

Other experimenters have sought more directly to devise instructional methods that can improve the efficiency of reasoning. In the U.S.S.R., Landa (1959, 1961, 1962) has devised "algorithms" for training pupils in "rational methods of think." Algorithms resemble computer flow charts, except that "they take into account the experience in thinking operations possessed by the child." The pupil is taught to go through a prescribed sequence of steps, each of which involves asking himself a specific question about the problem material and performing one of a set of alternative operations in accordance with the answer to the question. Landa has applied this method, which draws on mathematical logic, cybernetics, and information theory, to geometry and to grammatical analysis and claims that it could enable problems to be solved more speedily, easily, and effectively.

In the United States, Crutchfield (Covington and Crutchfield, 1965; Crutchfield, 1966) and his associates have produced written and pictorial material, resembling comic strips, that is designed to "promote generalized problem-solving skills" in fifth- and sixth-grade children. A child is taught "the value, necessity, and techniques of identifying and defining a problem properly, of asking ques-

tions and taking time for reflection rather than leaping to conclusions, of looking carefully at details and searching for discrepancies, of generating many ideas and not fearing to come up with what may seem 'silly' ideas, of looking everywhere when stymied for possible clues and sources of ideas, etc." He is given opportunities to generate his own ideas and receives "immediate and frequent feedback" in the form of "good examples of fruitful questions and hypotheses." Preliminary studies have indicated "substantial increments in the performance of the trained children on a variety of criteria and tests of problem-solving and creative thinking."

MOTIVATIONAL FACTORS

During the last 100 years, there has been a great accumulation of data on how both adults and children think when a psychologist has just instructed them to do so. Remarkably little is known about the conditions that govern spontaneous thinking in early or later life. It is, of course, obvious that effects resembling those that result from verbal instructions to think can be induced by other factors in everyday life outside the laboratory, for example by a subject's self-instructions or their equivalents. But all too little attention has been paid to the problem of exactly how words uttered by an experimenter can set thought processes in motion so powerfully and exactly what other conditions can and cannot have the same kind of influence.

In other words, the investigation of the motivational factors that underlie thinking have been woefully neglected both by specialists in adult thinking and by specialists in children's thinking (see Berlyne 1960a, 1965a). The factors that need to be identified if the so-called motivational aspects of thinking are to be illuminated include those that determine when a piece of directed thinking will begin, why it is aimed at one problem rather than at others, how long a thought process will persist, and when it will be terminated either through discouragement at lack of success or through recognition that a solution has been attained.

There are nevertheless some directions in which we may seek hints concerning these matters.

Exploratory Behavior

There has been a great deal of experimental work on the determinants of exploratory responses in children (Berlyne, 1960a, 1966b, Cantor, 1963). Exploratory responses—which may include eye movements, head turning, locomotion, and manipulation—have in common the function of introducing, intensifying, or prolonging “indifferent” stimulation, that is, stimulation that is not detectably accompanied by biologically important effects on the organism apart from the sense organs and the nervous system. It is clear, however, that such stimulus-seeking behavior can perform several sharply different biological functions and that indifferent stimuli may be sought for various reasons.

One distinction (Berlyne, 1960a) that has appeared more and more important as research has proceeded is that between “specific” and “diversive” exploration. Specific exploration is likely to occur when the organism is disturbed by a specific lack of information (uncertainty), and it is directed toward portions of the external environment that may supply the information through which the uncertainty-induced discomfort (perceptual curiosity) can be relieved. Diverive exploration, which includes several, if not most, of the activities that we classify as “play” (Berlyne, 1969), is aimed at stimulation, regardless of source, that possesses characteristics such as novelty, surprisingness, and complexity to the right degree.

Other writers have been led by their observations to suggest essentially the same dichotomy. Lewis, Kagan, and Kalifat (1966), discussing eye movements in infants, state that “there appear to be two causes of long fixations: (1) a preference created by the pleasure derived from looking at the stimulus and (2) a desire to categorize a stimulus or comprehend its meaning.” These clearly correspond to diverive and specific exploration, respectively. Likewise, Hutt (1966), who studied the behavior of 3- to 5-year-old children confronted with a rectangular box bearing a lever and four counters, distinguished two successive phases. First, there was “investigation” (i.e., specific exploration), during which “all receptors were oriented towards the object, the general expression being one of ‘concentration.’” The goal of this behavior was “getting to know

the properties.” When the child “feels he knows the properties of the object in that environment,” specific exploration gives way to “play.” “vision and manipulation were no longer simultaneously directed toward the object” and “the behavior towards the object might almost be described as ‘nonchalant.’” There was a “gradual relaxation of movement” and, in this phase of evidently diverive exploration, “the emphasis changes from the question of ‘what does this *object* do?’ to ‘what can *I* do with this object?’”

Of these two forms of exploratory behavior, the diverive form may have more affinities with autistic or free-associative thinking, but directed thinking and reasoning must be more closely related to specific exploration. Thus specific exploration and directed thinking are aimed at access to information that can relieve specific subjective uncertainties. Both can be regarded as means of relieving an aversive condition due to lack of information. Both seem to arise from the kinds of motivational condition that, in everyday parlance, we call “curiosity.”

There are, however, important differences between specific exploration and directed thinking. Whereas specific exploration leads to appropriate external stimulus patterns, directed thinking is a form of “epistemic behavior” (Berlyne, 1954, 1960a), which means that its function is to supply “knowledge” or information stored in verbal or other symbolic stimulus patterns. Some epistemic activities, notably consultation (which includes directing spoken or written questions at another person or looking up reference books), bring the subject into contact with external symbolic formulas. Directed thinking, on the other hand, constructs patterns of symbolic responses inside the subject, whose stimulus aspects are then capable of guiding overt behavior in conjunction with external stimulus situations.

Specific exploratory responses are usually evoked by stimuli that are novel, surprising, complex, or ambiguous (Berlyne, 1960). These and other “collative” stimulus properties (properties dependent on comparison of two or more stimulus patterns) generally entail subjective uncertainty about inaccessible properties of the stimulus object or event. There have been several competing analyses of the essence of the collative stimulus properties,

accounting for their motivational effects (Berlyne, 1963, 1965). Whichever precise formulation is favored, it is recognizable that they work by setting up discrepant processes in the central nervous system. They can be argued to motivate through *conflict*, which means, in the most general sense of the term, a condition in which mutually interfering processes occur simultaneously and in which selection of a motor response from a set of competing alternatives is therefore hampered.

In the case of the "problems" that give rise to directed thinking, and to epistemic (knowledge-seeking) behavior generally, not only is the "solution," the pattern that resolves the uncertainty, symbolic in form. The motivating conflict, whether it arises from contact with a puzzling external object, exposure to a puzzling verbal message, or immersion in a puzzling train of thought, is usually "conceptual conflict" or conflict between incompatible symbolic response tendencies. In other words, although extraneous sources of motivation may play an important part when thinking is aimed at the solution of a "practical" problem, directed thinking, it would seem from this line of argument, is initiated and kept going by factors stirring up mutually discrepant beliefs, attitudes, and trains of thought.

✓ Piaget's Equilibration

Piaget (1957, etc.) has asserted that the major advances that mark the child's progress from less mature to more mature ways of perceiving and thinking are brought about chiefly by a process he calls "equilibration."

- This is a tendency for systems of conceptual and intellectual activities to form structures of progressively more complete equilibrium. Although he concedes that learning and maturation have their contributions to make, equilibration is deemed distinct from either of them. Piaget discusses equilibration in relation to the major transitions of intellectual development, such as the transition from unorganized, haphazard perception to the "perceptual activities" that mitigate "primary" illusions and the transition from "intuitive" to "operational" thinking. It seems reasonable, however, to suppose that similar factors will account for the initiation of a specific piece of thinking as well as the adoption of new overall strategies of thinking and the con-

struction of the comprehensive systems of thought elements on which every specific thought process depends.

Piaget (e.g., 1967) dissociates equilibration from maturation on the grounds that the "dynamic structures" that underlie thinking are not innate but form very gradually. The stages that mark their construction do not correspond to a particular age but occur in a constant order of succession. Maturation simply fixes the limits beyond which development spurred by other factors cannot go. These points seem, however, to be equally applicable to aspects of behavior, like grasping and locomotion, that are generally cited as products of maturation. As for learning, Piaget and his associates (Gicéo and Piaget, 1959; Goustard et al., 1959) have gathered evidence that the phenomena attributed to equilibration are not produced simply by exposure to external events illustrating logical and mathematical principles. This is the main basis for his distinction between equilibration and learning. But the view that learning results simply from experiencing external stimuli in particular sequences was characteristic of the eighteenth-century empiricists and the nineteenth-century associationists. It is not typical of the contemporary learning theorist, although Tolman (1932) admittedly put forward a rather similar conception in modern times.

We may conclude, rather, that what Piaget calls "equilibration" is a form of learning, limited by maturational factors, that is motivated by conflict and reinforced by conflict reduction (Berlyne, 1960b, 1965; Ranzini and Tampiari, 1966). This can be seen from some of the rather meager hints that Piaget has thrown out regarding the essence of equilibration. He says (1957), for example, that progressive equilibration makes for increasing ability to predict and *sécurité* (assurance, security, safety). It therefore seems to be a matter of relieving subjective uncertainty. Equilibration also means a balance between "assimilation" (determination of behavior by factors inside the organism) and "accommodation" (determination of behavior by properties of external objects). It therefore evidently minimizes conflict due to discrepancies between external stimuli and expectations, beliefs, or habits derived from previous learning. Equilibration is said to result from

recognition of the inconsistency of judgement to which less mature forms of perception and thinking lead. The importance of conflict has received some confirmation from Smedslund's work (1961a, b) showing how conservation of quantitative invariants can be speeded up by a technique that forces a child to face the latent inconsistencies among his thought structures. Several new educational techniques (particularly the so-called "discovery" methods—see Berlyne, 1965b) seem similarly to improve retention and understanding by confronting a child with experience that reveals the gaps and discordances in his present knowledge.

Questions

Still further evidence on the development of motivational factors with relevance to thinking comes from studies of children's questions.

A question addressed to someone likely to know the answer is an epistemic response that often forms an alternative to directed thinking. We must thus suppose that these two epistemic activities have common sources of motivation. A question, whether put by somebody else or put to oneself, frequently starts off and directs a thought process. Furthermore, just as the existence of information (whether in the technical mathematical sense or in the everyday sense) necessitates prior uncertainty and just as curiosity is a product of previous knowledge supplying alternative hypotheses and competing response tendencies, a question is likely itself to be a product of previous thinking, from which subsequent thinking issues.

Studies of Spontaneous Questions

As Piaget (1923, Chap. 5) says, "There is no better introduction to child logic than the study of spontaneous questions." One might add that these questions must also have a great deal to tell us about the conditions that motivate recourse to logic. Fahey (1942) has supplied a useful review of empirical work and theoretical views on children's questions up to the end of the 1930s.

In the early days of child psychology, when day-by-day observation of individual children, usually the investigator's own offspring, was the standard source of information, plentiful collections of questions uttered by chil-

dren in the course of their normal activities were accumulated and analyzed. Several works belonging to this period (e.g., Stern, 1914, Piaget, 1923) differentiate two phases. The first phase begins at about the age of 1½, when the child has discovered that everything has a name. It is characterized by an abundance of requests for names of objects and also of questions about place. Around 2½ begins the second phase, in which why-questions and when-questions predominate.

Piaget's (1923, Chap. 5) penetrating analysis of 750 why-questions asked by one boy between the ages of 6¼ and 7½ led him to distinguish a number of categories. There were requests for *explanations* (in terms of either *cause* or *end*) with reference to physical objects, requests for *motivation* with reference to psychological actions, and requests for *justifications* with reference to customs and rules or (logical justification) with reference to classification and connection of ideas. Piaget agrees with Stern that the earliest why-questions are not expressions of curiosity but rather simply expressions of "wonder at what is unusual" (Stern, 1914), of an affective reaction to "disappointment produced by the absence of a desired object or the non-arrival of an expected event, i.e., surprise and frustration." This tallies with the fact that these earliest why-questions do not seem to call for answers, the child will, in fact, sometimes answer them himself. A little later, however, the child is evidently directing why-questions at adults in the hope of having something explained to him, but both his questions and his reactions to the answers that he receives manifest "precausal" thought, in which physical causality, human intentions, and logical deduction are not clearly separated. It is interesting that, when conversations between two boys of about the same age were recorded (Piaget, 1923, Chap. 1), a very small percentage of the questions that passed between them were "whys." Causality, as Piaget points out, "remains the subject of conversation between children and adults or the child's own solitary reflection." Consultation of adults and directed thinking are evidently the only epistemic activities that are regularly rewarded by receipt of curiosity-reducing explanations.

To return to the first boy, questions that

did not begin with "why" consisted of questions relating to *causal explanation, reality and history, human actions and intentions, rules and usage, arithmetical relations, and classification and evaluation*.

A somewhat similar study, with concentration on why-questions, was carried out by Isaacs (1930). He disputes many of Piaget's points, particularly those that emphasize differences between the causal thinking of children and adults. He also goes further in analyzing the conditions that motivate why-questions, seeing the crucial factor as "a certain clash, gap or disparity between our past experience and any present event." When this occurs, "immediate experience turns into a sense of something wrong with knowledge, some unsuspected error, insufficiency, or confusion—or of something wrong with the perception of a supposed fact." So the role of conceptual conflict, which was recognized by Stern and Piaget, is brought out even more clearly.

Statistical analysis was applied to large samples of children's questions by McCarthy (1930) and by Davis (1932). Questions were found to appear at a faster rate in boys and in children of higher socioeconomic status. The rate increased with age up to about 30 months and then remained fairly steady for some years after. The incidence of different types of questions also varied with the same variables. Both authors found questions to occur much more frequently when a child is talking to an adult than when he is talking to another child.

Studies of Induced Questions

In children of school age, questioning has generally been studied by procedures that induce or invite questions. The early literature of this kind is also covered in Fahey's (1942) review.

Yamamoto (1962) has analyzed questions produced by 850 subjects (grade-1 to grade-12 children, as well as adult counsellors) who underwent an "Ask and Guess Test." The subject is shown a picture illustrating a familiar nursery rhyme. In the first part of the test, which is the only part of interest here, the child is instructed to ask as many questions as possible about what he sees in the picture. The number of questions asked tended to increase with age. Ques-

tions beginning with "why" were commonest, they comprised 70% of the questions asked by grade-1 to grade-3 subjects, but their incidence dropped at grade 4 and higher, while questions beginning with "what" became more frequent. "Be?" questions (i.e., questions inquiring whether or not something is the case) become more frequent with age throughout the range. To sum up, children appear to advance from "global" questions (why?) to "specific" questions (what?, when?, where?, who?, and which?) and finally to "definitive" questions (how?, and be?).

Aikawa and Horiuchi (1962) solicited why-questions from 1028 children between grades 2 and 9. The number of questions supplied reached a peak at grade 6 and then declined. Why-questions about "human life" increased with age, while why-questions about "things" and about "animals and plants" became gradually less frequent. Why-questions regarding "natural phenomena" rose from grades 2 to 4 and then became less numerous. Boys asked more why-questions about "heavenly bodies" and "instruments" than girls but fewer about "animals and plants." The authors conclude that a phase of "materially cognizing reality" corresponds to late infancy and early childhood, whereas, after a transitional level occupying middle and late childhood, there is a phase of "socially cognizing reality" coinciding with pre-adolescence.

In an experiment by Stirling (1937), questions were elicited while children were exposed singly to a variety of pictures and stories. Questions were more numerous, and bore on a large number of items, the older the child was. Older children also asked more questions about purposes, times, and places, and fewer about names and attributes of objects. The number of questions also increased with IQ and socioeconomic status.

This technique was extended by Berlyne and Frommer (1966), who used pairs of items—pictures, orally related stories, orally related stories accompanied by pictures, and a magic trick—representing different values of "collative" variables (Berlyne, 1960), such as novelty, surprisingness, incongruity, uncertainty, and amount of information. The subjects ranged in age from kindergarten to grade 6. Over all age groups there was evidence that novelty, uncertainty, incongruity,

and surprisingness increased the incidence of questions. Number of questions increased with age in two of the schools from which subjects were taken but reached a peak in grade 3 at the remaining schools. This is likely to have been because the older children at this school turned out to be familiar with some of the stories that were used. Provision of answers to the questions increased the incidence of questions in grade-3 children but not in younger or older children. The authors suggested that "in the youngest children, the potential reinforcement value of answers may not have been operative and, in the older children, some other factor may have made up for the lack of answers when they were not forthcoming."

At all ages, specific interrogations (questions beginning with an interrogative adverb) were commoner than yes-no questions (questions asking whether a particular proposition is true or false). Explanatory questions were more numerous than factual questions when children were faced with a surprising magic trick, but factual questions were commoner in situations where facts were conspicuously lacking, that is, with exposures to a picture of a boy or a girl not accompanied by oral information and with exposure to stories of uncertain outcome. Explanatory yes-no questions, which require formation of an explanatory hypothesis, were found to an appreciable extent only among older (grade 5) children exposed to surprising magic tricks. When confronted with a story of uncertain outcome, the proportion of children asking which of the alternative possibilities was realized went up with age, but most children below grade 3 did not ask such questions.

Questions in the Course of Problem-Solving

The vital role of questions, and especially of well chosen questions, in directed thinking is illustrated by two experimental studies.

Luubinskaia (1948, cited by El'konin, 1960, p. 262, and Zaporozhets, 1964, pp. 210-211) observed preschool children faced with practical tasks and distinguished two kinds of verbal reaction: "play speech," reflecting emotional reactions to the situation, and "questioning speech," which is "directed to the establishment of new connections and relations as yet unknown to the child" (Za-

porozhets, 1964). Questions about causes were likely to occur when the child was faced with some difficulty, such as the failure of a toy to work as expected. To quote from Zaporozhets's interpretation, "The appearance of such questions is extremely important, since it attests the occurrence within the child of the first representations of the presence of causal relations. Furthermore, these questions exert an essential influence on the very process by which the child solves a practical task, imparting to his actions a striving for a correct solution, and imparting to the thought process a definite direction." In the youngest children, attempts to remedy an impediment have a chaotic character, but a question put by an adult can induce them to look for causes and to endeavor to put things right in a goal-directed and organized way. After experience of such interaction with adults, the child learns to put appropriate questions to himself spontaneously, and the formulation of a question, even in such a general form as "What's in the way?" or "What's gone wrong?", can make his search for an appropriate course of action more effective. The ability to do this in the face of practical problems comes, as one might expect, rather earlier than the ability to do it in the face of more abstract problems requiring logical inference.

Two variants of the "Twenty Questions" game were used by Mosher and Hornsby (1966) with children between 6 and 11 years. It is well known that the most rational strategy for games of this kind is what these authors call "constraint seeking," which means asking questions that narrow down the range of possibilities progressively and have equal chances of being answered affirmatively and negatively. The opposite of this strategy is what they call "hypothesis scanning." "A child simply asks a series of questions, each of which tests a self-sufficient, specific hypothesis that bears no necessary relation to what has gone before." In a first experiment, the children were confronted with 42 pictures of common objects and had to find out which one the experimenter had selected. Almost all the questions asked by 6-year-old subjects were of the "hypothesis-scanning" type. "Constraint-seeking" questions were somewhat more numerous than these at age 8 and comprised almost 80% of questions

asked at age 11. When 8-year-old children asked a constraint question, it was usually followed by a series of specific-hypothesis questions rather than by further constraint seeking. On the other hand, 11-year-olds generally avoided voicing specific hypotheses until they felt ready to terminate the inquiry.

A second experiment used verbally described situations. For example, subjects were told, "A man is driving down the road in his car. The car goes off the road and hits a tree," and they had to find out what caused the accident. Here, in contrast with the first experiment, where the alternatives were restricted to a set of pictures in front of the subject, the possible solutions came from an unrestricted universe. As before, 11-year-olds used constraint seeking more often than hypothesis scanning. But at the ages of 6 and 8, there was more partiality for hypothesis scanning than in the previous experiment. Furthermore, the percentage of children who asked connected series of questions, "basing later questions upon answers obtained earlier," rose from 40 at the age of 6 to 80 at the age of 11. Interestingly enough, when children were offered a choice at the beginning of the game between a general and a specific question, one-third of the 6-year-olds and most of the 8-year-olds actually chose the general constraint-seeking question. As the authors put it, "They appeared able to recognize a better strategy in the verbal game, but they seemed less able to mount the strategy on their own initiative."

A related investigation has been conducted by Olson (1966). Children were presented with a board bearing a number of light bulbs arranged in a matrix pattern. They were told that some of the bulbs, but not others, would light up when pressed, and two diagrams representing alternative partitions of the matrix into active and inactive bulbs were shown. The subject had to find out which of the two diagrams represented the true state of affairs, and this entailed pressing bulbs on the board in order to see whether each of them would light up or not. These bulb-pressing responses were thus equivalents of questions. Three-year-old children pressed bulbs in a "somewhat orderly" manner but independently of the diagrams representing the alternative combinations. At 5 years of age this behavior was generally replaced by

a "circuit-pattern-matching strategy" the child tried out each of the alternative solutions in turn, confining himself to bulbs that, according to the diagram, should light up. Finally, at about age 7, the "information-selection strategy" appeared. The child concentrated on "informative" bulbs—bulbs that would light up according to one solution but not according to the other and could thus offer a way of deciding between the alternatives rapidly. The author points out that the transition from the kind of search characteristic of the 3-year-old to the pattern-matching of the 5-year-old requires "not only the achievement of recognition of correspondence between a model and its referent, but also an achievement of the ability to reproduce." There must be "some interplay between the image and the action that it must guide." The information-selection strategy necessitates "being able to deal not with one image at a time, but rather with the properties or features of several images simultaneously." "Such a step," Olson writes, "corresponds to the development in the Twenty Questions game when children are able to ask 'indirect' questions about constraints, rather than testing hypotheses directly."

Procedures for Training in Questioning

As Mackworth (1965) has emphasized in a lecture on "Originality," "problem finding is more important than problem solving." Guilford (1956, 1967) has identified a dimension of "sensitivity to problems" as an important component of ability to think creatively. It is thus far from surprising to find questions assigned a prominent role in some of the newer pedagogical techniques, with their stress on training for creative problem-solving.

Some of the "discovery" methods confront children with questions and require them to find the answers to them through their own efforts. Others make the child formulate his own questions as an incentive and guide to fruitful discovery. There has therefore been considerable interest in the possibilities of training children to formulate questions more effectively and readily.

One notable example is the "Inquiry Training" project (Suchman, 1959, 1962, 1963). A procedure developed under its auspices begins with a short film demonstrating a

surprising physical phenomenon (e.g., a brass ball that is small enough to pass through a ring case can no longer do so after it has been heated). This is followed by "episode analysis" (Stage I) or a verification that the content of the film has been correctly noted. The children are then invited to discover the principles governing the phenomenon they have witnessed. They do so by putting questions to the teacher. The questions must be ones that can be answered "yes" or "no" and correspond to possible experiments that could be performed.

This constitutes Stage II, aimed at "isolation of the relevant variables and necessary conditions" and "identification of conditions that are necessary for the outcome of the film demonstration." Then, Stage III is devoted to "induction or relational constructs." Hypotheses regarding physical principles and relationships must be formed, and ways in which they can be tested must be conceived. A validation study, comparing children exposed to the inquiry-training procedure with others who were simply exposed to the film and then to more conventional teaching, indicated that "The inquiry skills of fifth-grade children can be improved over a 15-week period." The total fluency of questioning was significantly greater in the experimental group, and, in particular, fruitful kinds of questions were more frequent.

Another, somewhat similar program has been tried out by Blank and Covington (1966). Their subjects, predominantly boys in grade 6, were divided into three groups. All were exposed to verbal descriptions of situations in which somebody had to make a choice between alternative courses of action. Group I went through an auto-instructional program, aimed at training them to tell when a question cannot be completely answered without additional items of information and to seek the additional items by formulating suitable questions. Group II had an "emasculated" form of the program, in which they were simply told that certain kinds of information were needed. Group III had no programmed material. The results of the auto-instructional program were tested in several different ways. There was a pretest and a posttest with oral and written problems. Then, performance on a science-achievement test requiring problem solving was measured.

Finally, teachers were asked to rate the children for participation in class discussions on scientific subject-matter. Between the pretest and posttest problems, there was a significant rise in the number of questions asked in Group I but not in the other two groups. Group I also exceeded the other two groups in their scores on the science-achievement test and in rated participation in class discussion.

Asking questions, like other forms of epistemic and exploratory behavior, has always to contend with competition from locomotor withdrawal or from withdrawal of attention as a means of reducing disturbance from novel or puzzling stimulus patterns. The educational system must presumably incline children toward approach and information-seeking, although this must not go too far. Excessive scrutiny of external objects and pondering before coming to a decision is characteristic of obsessive-compulsive neurosis. Children must presumably be taught to judge when persistent exploratory and epistemic efforts are worthwhile and when they are not worth embarking on or should be abandoned. If relatively brief training programs, such as those just described, can incline the child to seek information and to construct questions that will enable him to do so efficiently, much must depend on the environment to which he has been exposed in his early years. The degree to which parents and teachers encourage a child's questions and answer them patiently and fully will, we must suppose, have lasting effects. Whether a child has been led into epistemic efforts that lie within his capacities and extend them progressively or whether he has been frustrated by unsuccessful attacks on problems that exceed his capacities will, no doubt, also have an important influence.

Profound differences between social classes and ethnic groups in aptitude and taste for schoolwork have often been noted. These differences could be due in part to motivational differences dependent on factors like these. In experiments on exploratory behavior, Lore (1965) found that lower-class "culturally deprived" children, at 6 or 7 years of age, spent less time looking at visual patterns than middle-class "culturally enriched" children of comparable age. The

difference in mean inspection time was particularly marked with irregular or incongruous (i.e., problem-raising or conflict-inducing) patterns. It seems likely that a similar difference would have emerged if epistemic behavior, including questioning and directed thinking, had been investigated instead.

Of late, considerable effort has been expended on working out teaching methods that

could improve the efficiency of children's reasoning. Future research must pay at least as much attention to the motivational factors that govern readiness to embark on thinking, skillful choice between thinking and alternative epistemic activities (consultation, observation), and the ability to judge when epistemic efforts are worthwhile and how long they should continue.

14. Concept Development

JOHN H. FLAVELL*

CONCEPTS

The search for a satisfactory definition of the term "concept" is a lexicographer's nightmare. Like its complex and elusive instances—"art," "life," "religion," etc.—this concept seems to defy all attempts at adequate epitomization. There have been many such at the topic begin with some sort of definition tempts, of course, nearly all writers who treat (e.g., Bruner, Goodnow, and Austin, 1956, Carroll, 1964, Harvey, Hunt, and Schroder, 1961, Hunt, 1962, Kendler, 1961, Klausmeier et al., 1965, Lange, 1948, Russell, 1956, Sigel, 1964, Vinacke, 1952). The various characterizations are far from identical, needless to say, and after pondering on them for a while the reader is tempted to think that their most important similarity is their common inadequacy. Each one leaves the reader with a sense that something has been omitted, distorted, or oversimplified—that something he intuitively feels to be true of at least some concepts has simply not been captured.

After further pondering he begins to suspect where the trouble lies. First, the array of entities that have been or could be included under the rubric "concept" is truly extraordinary. Second, a search for attributes common to this array gives meager returns. The

number of attributes is small, their applicability to the entire array is often dubious, the insight they give into the essential nature of concepts is frequently uncertain. Third, and in contrast, these entities differ from one another in an astonishing number of ways, the dissimilarities are, in fact, far more striking, clear-cut, and important-looking than the similarities.

Given this preponderance of differences over similarities, it is little wonder that the definitional enterprise has been so difficult, and its outcome so universally unsatisfactory. But if the concept cannot be tightly defined, the concepts can certainly be described and discussed with profit. It is very instructive to look at putative similarities among concepts and see what problems emerge, it is probably even more instructive to examine some of the important differences, because the richer story lies there. Concepts are usually regarded as the fabric of mental life. It is not surprising, after all, to learn that the former is as complex and baffling a notion as the latter, and just as resistant to easy characterization.

Similarities among Concepts

Concepts as Equivalence Responses. One of the most serious contenders for the status of common attribute here is the notion of equivalence response. The argument is that all concepts imply similar or identical reactions to different environmental inputs. Kendler actually goes so far as to define concepts entirely in terms of "a common response to dissimilar stimuli" (1961, p. 447). This view of the nature of concepts leads to further assertions of considerable importance. For one thing, it explicitly locates concepts in orga-

* The author wishes to express his deepest appreciation to Samuel R. Cannizzo, Marvin W. Daehler, Terry G. Halwes, Barbara E. Moely, and Frances Wynns Knudtson for their bibliographic assistance in the preparation of this chapter. He is also much indebted to Joachim F. Wohlwill for his invaluable contributions to the ideas (at least the better ones!) presented in the final section on general issues.

nisms rather than in their external milieu. Carroll (1964) has observed that there could be no concepts in a totally inorganic world because they are "properties of organismic experience" (p. 180). In addition, this view indicates a semantic connection between "concept" and such terms as "class," "category," and "set," inasmuch as the latter also imply, psychologically speaking, an act of colligation or drawing-together of disparate elements for response purposes. Furthermore, it is always assumed that the organism has an organized network of such equivalence responses, and this implies discrimination as well as generalization. That is, the individual makes one response to one set of inputs, a different response to a second set, and so on.

The concept repertoire serves in this way to carve up or "chunk" the organism's entire world into functional units, yielding a complete mapping of responses into stimulus sets for the length and breadth of the psychological environment. Harvey, Hunt, and Schroder well describe, in the case of human organisms, this structuring-of-the-world function of concepts.

We assume that an individual interacts with his environment by breaking it down and organizing it into meaningful patterns congruent with his own needs and psychological make-up. As a result of this interchange, perceptual and behavioral constancies develop, which stem from the individual's standardized evaluative predilections toward differentiated aspects of his external world. We will refer to such evaluation tendencies as *concepts*.

A concept is a system of ordering that serves as the mediating linkage between the input side (stimuli) and the output side (response). In operating as a system of ordering, a concept may be viewed as a categorical schema, an intervening medium, or program through which impinging stimuli are coded, passed, or evaluated on their way to response evocation (1961, p. 1).

And further:

Once a concept develops, it serves as an experiential filter through which impinging events are screened, gauged, and evaluated, a process that determines in large part what responses can and will occur (pp. 2-3).

Difficulties in identifying concepts with equivalence responses. There appear to be two problems in defining concepts as equivalence responses. First, it is uncertain whether all concepts literally entail equivalence responses and, more generally, whether a description in terms of "equivalence" and "response" always gets to the heart of what is really involved in concept making and concept using. Second, it is similarly questionable whether all reactions which are indisputably equivalence responses are equally indisputably concepts.

For the first, the following statements seem to be true of at least some *prima facie* concepts: (1) the concept need not be acquired at all, (2) if acquired, it need not be acquired through a process of successive common responding to the different relevant objects, (3) there may in fact be only one such object to which the concept can apply, and hence the "equivalence" part of the characterization is not literally applicable.

1. A given organism may be genetically programmed to respond in a certain way to a specific set of inputs. There would be some discomfort, however, in asserting that it does not possess this "concept" prior to actually making the response across the stimulus set in question, that is, the assertion that the concept *is* the equivalence response seems forced.

2. I may acquire a given concept without constructing it from successive contacts with the relevant instances. I may, for example, attain an impeccable concept of "centaur" without ever "responding" to a set of pictures of centaurs, and would certainly have to do so without contact with instances of the real article. Again, an identification of concept and actual responses to concept instances seems unwarranted.

3. When the first wheel (of automobile, or digital computer,) was built, there was by definition only one concept instance, there was and always will be but one exemplar of constructs like "Minoan Civilization." Some will recoil before the prospect of saying that the inventor of the wheel could not have a concept of one until a second was built, or that "Minoan Civilization" simply can never be a concept because it has no plural.

It is not argued that the notion of equivalence

lence response cannot be made to apply in such cases, especially if it is liberalized to include response "dispositions" and "potential" equivalences. The animal, of course, could and certainly would make its innate response to the relevant stimulus set, given the opportunity, my concept of "centaur" would presumably allow me to "respond appropriately," should I chance to encounter such a creature, and the specialist could doubtless identify new instances of that ancient civilization as such, were these instances somehow to be created for him. The point is rather an uncertainty of how far the notion brings us in understanding how people, in particular, develop and utilize concepts. That they can and do use them to order and collectivize real sensory input is undeniable. The question is to what extent they do other, perhaps more important, things with and to their store of concepts, especially in the *absence* of any sensory input regarding concept instances.

The second difficulty with the criterion of equivalence response is that it buys us some "concepts" we may not want to pay for. I respond to all members of one diverse class of stimuli by sneezing, any member of another group of inputs makes me drowsy. Certain fish react by fighting all and only those intruders into its territory who bear certain markings. Indeed, even plants make what are essentially invariant responses to variant inputs. These and many other humble reactions appear to fit the definition of equivalence response, but most people would be loathe to apply the designation "concept" to them. Actually, it is difficult to avoid the conclusion that equivalence responses are intimately involved in adaptational patterns at all biological levels, and that identifying concepts with such responses virtually makes them synonymous with biological adaptation itself. To paraphrase Carroll, perhaps there could be no organic life without equivalence responses, as well as no concepts without organisms.

The only escape from this difficulty would be to restrict further the definition of a concept by adding new criterial attributes. Concepts would then be construed as but one species of equivalence response, a species whose special properties sharply distinguish it from other, nonconceptual equivalence responses. But what might these special properties be? The writer, for one, has been un-

able to find any satisfactory conjunction or disjunction of additional attributes that would delimit the class in an intuitively satisfying way.

One can, of course, always impose *arbitrary* criteria for one purpose or another—simply to constrain the behavioral domain one wants to investigate, for instance. Thus Hunt (1962) excludes all inhuman equivalence responses from his definition of a concept for just this reason. What seems to be lacking so far is a *principled* distinction, one that suggests fundamental differences in process and mechanism between those equivalence responses we wish to call "conceptual" and all other kinds. While such a distinction may emerge when we learn more about these processes and mechanisms, none seems available at present.

Functional Similarities among Concepts It is plain, then, that all problems in the conceptualization of concepts are not resolved by appeals to the notion of equivalence response. At the same time, there is obviously something of value in looking at concepts from this point of view. Concepts *do* serve to partition the subject's world into functional units, as nearly everyone has suggested. Moreover, interpreting concepts as equivalence responses leads to some plausible guesses about their adaptational values, about what they accomplish for the organism. That is, the selection of equivalence response as a formal similarity facilitates the identification of some likely functional similarities as well.

Bruner, Goodnow, and Austin (1956) have described several properties of this kind. First and foremost, concepts have the absolutely essential function of reducing the complexity of sensory input to manageable proportions. As they put it, "categorization serves to cut down the diversity of objects and events that must be dealt with uniquely by an organism of limited capacities" (p. 245). This simplification function has important consequences. For one thing, it allows the organism a viable economy of time and effort in dealing with the world. Old and new inputs alike usually can be quickly identified and appropriately reacted to by virtue of being assimilable to existing concepts. For another, it leads to the possibility of a highly adaptive anticipation of future events from present events. To know that a perceived object is an instance of a particular class is to know a great deal else

that is not immediately perceptible it is to know virtually all that it could do to you or you to it, because this information is implied in its class membership

It is this future-oriented aspect of categorizing behavior in all organisms that impresses us most. It is not simply that organisms code the events of their environment into equivalence classes, but that they utilize cues for doing so that allow an opportunity for prior adjustment to the event identified (Bruner, Goodnow, and Austin, 1956, p. 14)

We regard a concept as a network of sign-significate inferences by which one goes beyond a set of observed critical properties exhibited by an object or event to the class identity of the object or event in question, and then to additional inferences about other *unobserved* properties of the object or event (*ibid.*, p. 244)

In sum, concepts perform a dual service: (1) they identify and classify input information, (2) they make it possible for the organism to "go beyond the information given" in all manner of adaptive ways. As Klausmeier et al. (1965) state:

Concepts serve two main functions in human behavior: as responses to objects and events by which they are classified and categorized, and as mediators between stimulating events and subsequent behavior (p. 5)

Conceptual Systems There is one further property which surely characterizes all "higher-order" equivalence responses—at least, that is, all responses everyone would be comfortable in calling "concepts": the contents of the individual's conceptual repertoire are complexly interrelated to form conceptual systems. The defining attributes of one concept will themselves consist of other concepts, and that concept will in turn assist in the definition of still others. The easiest way to gain a sense of the extreme interconnectedness of concepts is to thumb through a dictionary. Most dictionary entries refer to concepts, and these concepts are of course always defined in terms of other concepts. Moreover, concepts make important mental liaisons with others which do not form their definitional

base, as every student of word association processes knows. In general, about the most certain prediction one can make regarding the psychological activation of any concept is that numerous others will be immediately activated in consequence. It is the fact that concepts are functionally interlocked to form complex systems, which gives the temporal flow of most thinking its smooth, continuous, and effortless quality.

The argument was made earlier that an equivalence-response characterization of concepts fails to convey all that we sense to be important about them. One thing it fails to convey is this extraordinary interdependence among concepts. Not only does the subject map sensory inputs into concepts, he also goes on to relate these concepts to numerous others. All things considered, it is not surprising that Harvey, Hunt, and Schiøder (1961) could write an entire book about conceptual systems.

Differences among Concepts

The diversity found in the realm of concepts is of two, roughly distinguishable sorts. First, there is variation associated with concepts taken in their public, consensually valid aspect. Although concepts are fundamentally private, cognitive phenomena, they of course can be and are externalized as social objects, and agreement can often be reached as to what their exact, "correct" meaning should be. Susanne Langer had this public and external face of the concept in mind when she defined it as "that which all adequate *conceptions* [i.e., private and internal conceptual acts] of an object have in common" (1948, p. 58, our italics and insertion). In other words, it is possible to look upon concepts as detached, ideal entities, unrelated to any individual's living cognitive experiences, and to discern a number of dimensions on which these entities vary.

In addition to this variation in the nature of concepts taken per se, there are also differences in their relation to the individuals who use them. Knowing that a given concept, as a public entity, has certain attributes does not tell me what it means to you, how you represent it to yourself, how and under what conditions you can access and utilize it—in short, its role and status in your cognitive life. Just as concepts differ among themselves, so also

do individuals differ in the way they apprehend, use, and otherwise "relate to" any given concept. Since this chapter is concerned with concept *development*, variations in the subject-concept relation among different individuals (younger versus older children) is of considerable interest.

Variation in Concepts One of the best available treatments of how concepts differ is given in Klausmeier et al. (1965), the classification given below is derived in part from their analysis. It will become apparent that the dimensions proposed are not the only ones possible, nor are they entirely independent from one another, they do, however, collectively give a fair image of the heterogeneity of concepts.

1. Attributes An object of perception or thought constitutes an instance of a well-defined concept if and only if it possesses the set of attributes given in the definition of that concept. Instances of the concept will invariably possess other, nondefining attributes as well. Some of these will characterize all the instances, just as the defining attributes do, others will characterize a greater or lesser portion, that is, they will be correlated at some level with the presence of an instance. For example, all mammals have hair and bones, and most are terrestrial, yet only the first of these three attributes is "criterial" for that class of animal. Noncriterial as well as criterial properties serve as cues for categorizing objects, however. I may be too far away from an animal to see whether it has hair or not, but I can still make an educated guess that it is a mammal from other, noncriterial cues (such as the region I am in, the animal's general shape and size, and the fact that I see it moving along the ground).

The attributes, criterial and noncriterial, associated with instance identification and concept use are a most heterogeneous lot. Literally anything that human beings are able to perceive or intellectually construct can serve as a conceptual attribute (recall the earlier remark that concepts have other concepts as their defining properties). An attribute may, for example, be some perceptible or measurable physical property of the instance, such as its color, texture, and composition. These are properties that generally come to mind in thinking about the criterial attributes of concept instances. But there are other at-

tributes, increasingly less concrete, immediate, palpable, and "intrinsic" (Klausmeier et al., 1965, p. 4) than these familiar prototypes. A large and ill-bounded group of attributes refers to function and activity rather than structure, to potentiality rather than actuality. Objects are not only "red," "smooth," "tall," etc., but also "edible," "combustible," "soluble," and the like. We categorize objects not only in terms of their immediate, static properties but also in terms of nonimmediate, "transformational" ones: what the object could do or become under certain circumstances, what we could do to or with it under certain circumstances.

There are other concept-defining attributes which "inhere" still less in the concept's instances. Careful examination of an object in isolation will permit the conclusion that it is "round," and even that it is "combustible," but no such analysis could serve to establish that it is a "nephew," a "logical conclusion," or a "best seller." The defining properties of many interesting concepts are less "attributes" in the literal sense than they are assertions regarding the role and status of their instances within some system of interrelated objects. One may have to know a whole complex of historical and current information about the object and its conceptual environment in order to determine that it is a member of certain types of class. As Jenkins has put it, certain concepts are best described as "constructs in general systems of relationships" (1966, p. 68).

2. Structure The meaning of a concept includes not only its set of criterial attributes but also an assertion about how these attributes must be interrelated or combined in the concept definition. Bruner, Goodnow, and Austin (1956) have distinguished three types of combination—*conjunctive*, *disjunctive*, and *relational*. If two properties must both be present for the object to constitute an instance of the concept, the definitional structure is conjunctive (e.g., a "bachelor" must be *both* male *and* unmarried). If the presence of either attribute suffices, it is disjunctive (e.g., *either* extreme social withdrawal *or* delusional thinking may win you the diagnosis of "schizophrenic"). If the relationship between the attributes must be of a certain kind, the structure is relational (e.g., "equilateral triangle" refers only to those triangles

whose sides are equal) Any one or combination of these three types of attribute pattern may obtain for a given concept

The nature and complexity of concept structure varies a great deal from concept to concept The conjunction of but two attributes suffices to define "bachelor" In contrast, the definitional structure of the legal concept "toit" is something like this (Carroll, 1964) $(A + B + C + D + E + F + G + H)(I + J)(K)(-L)(-M)(-N)(-O)$, where the letters refer to attributes (each one itself a structurally complex concept, be it noted), the plus sign to disjunction, the parentheses to conjunction, and the minus sign to absence of In the same notation, "bachelor" would be described as $(A)(B)$

Notice that disjunction, in contrast to conjunction and relation, serves to unite what may be very different objects under the same conceptual roof A batter can fail to get on base (be categorized as "out") in quite a variety of ways We all are accustomed to thinking of concept instances as possessing "common attributes" It became evident in the preceding section, however, that the elements of a concept's definition are often "attributes" only in the loosest sense And in the case of disjunction concepts, the modifier "common" is equally inexact and misleading

3 Abstractness A concept is said to be "concrete" to the extent that its instances are tangible objects, and "abstract" to the extent that they are not Thus "dog" and "telephone" would be categorized as concrete concepts, whereas "eternity" and "democracy" are abstract ones The view that concepts are made up of other concepts is nowhere more evident than in the case of such abstract entities: their components are entirely conceptual—attributes, instances, and all

4 Inclusiveness Concepts vary in the number of instances they include A concept may have no instances ("Sumerian jet pilots"), a small number ("North American countries"), a large number ("grains of sand"), or an infinite number ("integers")

5 Generality Concepts also vary in their position in the classification hierarchy to which they belong, the higher they are in the taxonomic tree, the more general they are By this definition, "mountain gorilla" would constitute a very specific concept,

"mammal" a more general one, and "organism" a very general one

6 Precision A concept is "precise" to the extent that our present knowledge would allow us to agree upon an explicit and workable set of rules for distinguishing instances from noninstances Some concepts are extremely precise by this standard, for example, "bachelor" and "equilateral triangle" Others, like "masterpiece," "schizophrenic," and "grammatical English sentence," are, by the same token, quite imprecise Most workaday concepts fall somewhere in between, and are often less precise than one would have thought (try writing an effective set of identification rules for "tree" contrasted with "bush")

The fact that one cannot formulate an explicit set of identification rules for a given concept does not necessarily mean that the users of the concept cannot identify instances with fair precision and consistency, that is, our inability to explicate these rules does not mean that they are not somehow represented, in an inarticulate and implicit form, in the subject's psychological structure A native speaker of English can quickly and effortlessly sort most strings of words into the two classes of grammatical/acceptable versus ungrammatical/unacceptable English sentences, but linguistic science cannot yet adequately formulate the rule system he is implicitly using when he does so (e.g., Chomsky, 1965) As a matter of fact, many of the most engaging research problems in the life sciences have to do with explicating some organism's "concepts"—with understanding the implicit rules that govern its invariant reactions to variant inputs

7 Power A concept is "powerful" if it satisfies two conditions (a) most people would agree that the concept is, for some reason, an important and central one, (b) its attainment makes possible or facilitates the attainment of a number of other important concepts Metaphors like "key," "cornerstone," and "building block" come to mind in connection with concepts of this sort, because of their special location and role within systems of interconnected concepts This dimension is of particular interest to developmental psychologists and educators, since it has to do with concept acquisition The child ac-

quires a multitude of concepts as he grows, but not all of them point beyond themselves to important further acquisitions. While the attainment of a concept like "cat" may not be wholly without significance for the child's overall intellectual growth, it scarcely has the formative, development-impelling power of "permanent object" or "measurement unit." It is such powerful concepts whose attainment the developmentalist wants to understand and the educator to foster.

Variation in the Subject-Concept Relation

1 Validity Although a given concept may have a relatively constant and fixed public meaning, it is obvious that individuals may differ widely in their private conceptions of it. There are two major variations here. First, the subject's operating interpretation of the concept may deviate from the accepted interpretation on any of a number of dimensions. His category may be narrower than the standard, or broader, or some distortion of it (for instance, what might be termed a "partial concept" or a "pre-concept"). The concept has one more or less definite meaning and individuals have various different approximations of that meaning. On the other hand, the individual's concept may deviate from the standard in that its meaning is less definite and fixed than that of the standard. Thus not only may it differ in meaning from the standard, it may also differ in meaning for the individual himself from occasion to occasion.

Both types of departure from validity can be noted in the ontogenetic acquisition of concepts (and also, of course, in the "microgenesis" of much adult new learning). For instance, Piaget's studies indicate that the young child's concept of, say, quantity tends at once to be different from and more unstable than the adult prototype. Quantity is likely to have a unidimensional rather than tridimensional meaning for the child ("more" means "taller" only, or "wider" only), and it may also refer to one dimension (e.g., height) in certain situations and another dimension (e.g., width) in other situations. An understanding of how certain powerful concepts stabilize and converge on their public prototypes during childhood is a major objective in the study of concept development.

2 Status It is ambiguous simply to say that someone "has" a certain concept, because concepts can be "had" in rather different ways. In particular, the concept may have only the status of a vehicle or instrument of adaptation, or it may also have in varying measure the status of a well-articulated and fully coded object of thought. An individual could not be said to have a concept if he could not in some sense think *with* it; he might well be said to have it, however, even though he could not in the slightest degree think *about* it. Thus the concept-user might have no name for or awareness of a given concept, or he might know its name without being able to characterize it further, or he might be a highly articulate authority on its full and exact meaning, its implications for all manner of things, and its place in whole systems of related concepts. Concept as cognitive object and concept as cognitive instrument are imperfectly correlated within individuals: if one has the former one is rather likely to have the latter, but the converse is hardly true—remember the earlier example, "grammatical English sentence." Children especially are very likely to "have"—that is, indisputably operate in terms of—concepts which they cannot name, let alone define and discuss.

3 Accessibility The old distinction between learning and performance applies to concept usage: an individual may have acquired a concept (of whatever validity and status) and yet, for any of a variety of reasons, be unable to gain access to and use it on some given appropriate occasion. The distinction is between what one knows—timelessly, as it were—and what one can do in this or that immediate situation. The hiatus between learning and performance can vary across individuals for the same concept and also within an individual across concepts.

In summary, the subject-concept relation may vary in at least the following three ways: (a) the nature and degree of resemblance between the subject's private conception and the public, "standard" concept (validity), (b) the extent to which the concept can function as intellectual object as well as intellectual instrument (status), (c) the extent to which the concept is available for use on appropriate occasions (accessibility). Onto-

genetic changes in validity have traditionally received the greatest research emphasis, but a full account of conceptual development ought to encompass changes in status and accessibility as well. In addition to being of intrinsic interest, the fact of these latter changes has implications for the assessment of validity. In trying to establish that a child has just recently acquired a certain concept (in final, adult form or in any more primitive form—the point is the same), the investigator may have to negotiate, as obstacles to his assessment attempts, the fact that the child may be utterly inarticulate about his concept and that he may also have trouble bringing it into active service in all but the most obvious and compelling situations. It is important to find out when the child first has a given concept “in some sense.” But when a concept is newly minted and freshly attained, it is likely to be unformulated, precariously utilizable, and therefore difficult to diagnose (Flavell and Wohlwill, 1969).

CONCEPT DEVELOPMENT

The research literature on concept development has grown so large that no chapter-length survey can cover it fully. We therefore set priorities for which studies to highlight, which to cite briefly, and which to exclude altogether. It will become apparent that some studies have been excluded from this chapter because, although relevant to concept development, they are better treated elsewhere in this book. For the remainder, the writer's biases have led him to emphasize investigations of the following kinds:

1 The investigation attempts to track some substantial and enduring developmental modification in the child's conceptual program. Not all studies involving concepts and using children as subjects do this. Many concept-formation or concept-learning experiments, for example, seem to measure the child's ability to utilize some concept he has already attained rather than assess his level of conceptual development. Although such experiments can certainly illuminate the learning and problem-solving abilities of children at various ages, their contribution to our understanding of concept development itself is often less apparent.

2 The concept under study has some *prima facie* importance as a cognitive acquisition. It may have considerable “power” as an adaptational tool or as a developmental formative (see previous section). Or it may appear to be a cognitive-developmental “universal,” that is, a concept that is probably acquired by all normal children in all societies.

3 The research gives evidence regarding some unexpected or surprising acquisition. It may never have occurred to us, perhaps, that the concept studied exists as an active, if implicit, component of the adult cognitive system. Or perhaps, knowing this, we are surprised to learn that the concept *needs* acquiring at all, that is, that young children typically do not possess it. Piaget's studies of the attainment of conservation concepts are examples of what is meant here.

4 The study sheds some light on the all-important problem of how the child makes cognitive progress, that is, concerning the mechanisms or processes underlying developmental movement. We know very little about the mechanisms of development at present, and any investigation that even touches on the problem has an immediate claim on our attention.

5 The study contributes something to a unified and integrated picture of conceptual development, in which various acquisitions are seen as functionally and temporally interconnected. The study may show, for example, how some concept slowly evolves through a succession of preliminary versions or pre-concepts. Or it may illustrate how certain attainments pave the way for later ones, which then play the same developmental role for still others. Or it may show how a certain concept, once achieved, enters into the construction of a whole array of disparate-looking attainments. In all such cases, the evidence presented reduces our sense of the heterogeneity of development by relating one acquisition to another, within and across time periods.

6 Implicit in most of the preceding points, the investigation was cast within or can be related after the fact to some existing developmental theory or pretheory. The study can thereby find its place within a larger body of research evidence dealing with the same theory and its data can be given a fuller

and more coherent interpretation. Nowhere do facts without theory stand in lonelier isolation than in the area of concept development.

If the reader interprets this discussion as meaning that he is in for a chapter featuring research in the Piagetian mode, he is of course right. Other recent reviews of conceptual development (Sigel, 1964, Wallach, 1963) have done the same thing, doubtlessly for the same reason. The reason is simply that, in this decade, there is really no other choice. Piaget-related studies comprise a large proportion of the existing publications on concept development, and a still larger proportion of the interesting ones (by the criteria just given—or by any other reasonable criteria). Furthermore, this is the only comprehensive and detailed theoretical system presently available in this area. This system has generated all manner of empirical findings to replicate and extend, specific hypotheses to test, and general issues concerning the nature of development to ponder and to translate into researchable problems. A contemporary survey of conceptual development research without a Piagetian emphasis would reflect not merely coolness and disinterest but an outright and peevish animus against his approach. Whatever may have been true in the past, few psychologists bear any such animus today.

For those who wish to pursue the subject of concept development more deeply than we do here, there are several useful sources. Piaget has recently written good summaries of his own work, in this book and elsewhere (Piaget and Inhelder, 1963, 1966). Other surveys and evaluations of Piagetian theory, research, or both include those by Baldwin (1967), Elkind and Flavell (1969), Flavell (1963a, 1963b), Hunt (1961, 1963), Inhelder (1962), Lovell (1962), Lunzer (1959, 1960a), Sigel (1964), Sigel and Hooper (1968), Wallace (1965), Wallach (1963), and Wohlwill (1962, 1963, 1966a). Wallace's book in particular—probably not well known in the United States—provides excellent coverage of non-Genevan research on Piaget's theory up to 1963 or so. There have also been two published conferences devoted to his approach (Kessen and Kuhlman, 1962, Ripple and Rockcastle, 1964).

Sigel's review (1964) also describes non-Piagetian research on concept development, as do earlier surveys by Russell (1956), Vinacke (1952), and Weiner (1948).

NORMATIVE-DESCRIPTIVE STUDIES OF CONCEPT DEVELOPMENT

THE LOGICAL AND MATHEMATICAL WORLD

Classes

In the first section of this chapter, it was asserted that the relationship between an individual and a concept may vary along the three dimensions of *validity*, *status*, and *accessibility*, and that this variation is partly a function of the individual's developmental level. Since "concept" and "class" are so closely related in meaning, these dimensions are especially pertinent to the present topic. We shall begin, then, by rephrasing aspects of these earlier remarks as they apply to a developmental analysis of classification behavior.

The entities called "classes" have a dual status in human cognition. On the one hand, they are usually regarded as essential ingredients of the thinking process itself. Particular classes are constantly being retrieved or constructed by the individual and pressed into service as conceptual vehicles or instruments. On the other hand, classes can also constitute abstract objects of thought. The individual may, in addition to utilizing particular classes in his everyday thinking, have explicit or implicit knowledge of the logical properties of classes and classification systems in general. The distinction here is between classes considered as cognitive tools and classes taken as the elements of a subject matter or body of knowledge—between the classes the subject knows and what he knows about classes.

Moreover, the classes available to the subject and the manner in which he can utilize them in thinking must depend, among other things, upon his grasp of the basic nature of classes and their interrelations. For instance, his ability really to understand and reason about the assertion that the object before him

is at one and the same time a beagle, a dog, a mammal, and a living organism must depend in part upon his tacit understanding of how logical classes—these or any others—may interrelate in hierarchical systems. Of course, what the individual knows about classes-in-general—his “metaconceptual” knowledge, as it were—will not be the only determinant of the categories he favors or his favored use of them. A disposition toward concrete, loosely organized categories in a young child is not explainable solely on the basis of an inadequate grasp of classificatory logic. On the other hand, advances in his understanding of the abstract properties of class systems will surely be one of the necessary conditions for the later formation and skillful utilization of higher-level categories.

If one turns to the developmental literature, it immediately becomes apparent that there is virtually no study in any area of conceptual growth that could not be construed as relevant to the development of classes-qua-intellectual-instrument (Wallace, 1965, p. 178). The child obviously classifies and categorizes phenomena within each of the conceptual domains treated in this chapter—number, space, causality, etc.—and the nature and manner of utilization of these categories change with age. For instance, the assertion that animistic thinking decreases with age can be paraphrased as the assertion that the child's implicit definitions of the classes “living” and “not living” undergo developmental alteration. There are some things to be learned about the development of the class-as-instrument aspect of the subject-class relation from the literature conventionally associated with this topic, for example, dealing with children's behavior on sorting tasks, but the intimate relation between “class” and “concept” should warn the reader to look beyond this literature (and this chapter section) for the fuller picture. As for the classes-qua-intellectual-object aspect, the pertinent studies are somewhat easier to demarcate. This area has been the particular province of the Geneva group, although there is also a good deal of non-Genevan research which bears on it directly or indirectly. For other treatments of the classification-development literature, see Vinacke (1952), Wallace (1965), and particularly Kofsky (1963).

The Beginnings of Classificatory Activity

When does the child begin to classify objects and events? Our earlier difficulties in defining “concept” versus “equivalence response” suggest that there can be no unambiguous answer to the question. If classification behavior is taken to include similar behavioral reactions to nonidentical inputs, then it is apparent that the very young infant is continually engaging in it. As Inhelder and Piaget (1964, p. 13) have noted, much of the infant's everyday activity looks analogous to what in the older child would unequivocally be called classifying (e.g., assimilation of diverse objects to a common sensory-motor schema). There is also evidence that the very young child tends to group related or associated items in his recall. Although most developmental studies of associative clustering indicate that it increases with age (Austin, Gekoski, and Zivian, 1965; Bousfield, Esterson, and Whitmarsh, 1958; Rossi, 1964; Rossi and Rossi, 1965), even 2-year-olds show a significant amount of it (Rossi and Rossi, 1965).

One might prefer instead to set as the beginnings of classificatory activity the age at which the child starts manually to group together similar or related objects. Although this criterion is no less arbitrary than any other, it has the advantage of referring to overt, observable behavior, and behavior closely resembling what has traditionally been accepted as an expression of classification skills, namely, what an individual does in an object-sorting task. Stott (1961) reports a spontaneous instance of such grouping in his 15-month-old son. He observed the boy systematically gathering together all the red bricks from a multicolored assortment, despite the fact that they were scattered randomly among the other bricks and therefore not always the easiest to reach. One would think that evidence on infant sorting behavior could emerge only from chance observations of spontaneous behavior, such as Stott's. However, Ricciuti (1965, Ricciuti and Johnson, 1965) has devised an ingenious procedure for eliciting it under laboratory conditions. Eight objects are spread randomly before the child, four of one class (e.g., stinging beads) and four of another (e.g., clay balls). The instructions are simply “See these?—You play with them—You fix them all up.” Ricciuti (1965) has tested infants as young as 12 months of age with this procedure, and

finds that some of them respond with such classificationlike behavior as serially touching, manipulating, or putting to one side all the members of one of the object classes (and, more rarely, both of the object classes). It is clear, then, that classificatory activity, whether broadly or narrowly defined, is in evidence during the period of infancy. As such, one must agree with Inhelder and Piaget (1964) and Ricciuti (1965) that its origins, at least, are not dependent upon the linguistic abilities so often associated with the notion of classification.

Classes in Isolation As would be expected, the great majority of studies in this area deal with postinfancy development. Following Kofsky (1963), we shall review the evidence under two headings. This section discusses the child's behavior vis-à-vis any given class taken in isolation, for instance, the structure of the class he forms as a result of grouping certain objects together. The next section will deal with developmental changes in his grasp of the interactions and interrelations among classes, for example, his understanding of the rules governing class inclusion within a class hierarchy.

Ricciuti's data (1965) provide a good point of departure for the evidence regarding isolated classes. From the standpoint of logical classification, the behavior of his young Ss was impeccable: there were two readily discriminable classes of objects, each with its own set of common perceptual attributes, and some of these children moved all (and only) the members of the one class away from the members of the other. If you gave the average adult the same objects and asked him to sort them, he would certainly have made the same division. Ricciuti subsequently retested some of his 20-month-old Ss when they were 40 months of age (Ricciuti and Johnson, 1965). Not surprisingly, the frequency of this logical-looking behavior had increased. What was surprising, however, was that these children also showed a grouping activity which had been largely absent 20 months earlier and which was distinctly illogical, from a strictly classificatory point of view. They would, for instance, form two aggregates, each containing two objects from *each* class, moreover, the objects within each aggregate were brought close together to form what looked suspiciously like a 3-year-old's

version of an interesting design or pattern. Ricciuti and Johnson argue quite plausibly that these patterns reflect intellectual progress. The 40-month-old can group objects together on the basis of both common attributes and then joint contributions to pleasing spatial configuration, the 20-month-old can only group by common attribute, a more purely classificatory activity. The fact remains that these 3-year-olds do show a form of behavior in a classification setting which adults rarely show. An examination of the literature further suggests that this particular form is but one of a number of dispositions or tendencies at the level of the isolated class which exhibit developmental modification. The existence of these various developmental changes is easy to document, as will be shown. Their interpretation remains somewhat obscure, however.

Olver and Hornsby (Bruner, Olver, and Greenfield, 1966, Chap. 3) argue that an individual's classification of a set of objects exhibits both "semantic" and "syntactic" features, and that both undergo developmental change. The semantics of classification refers to the features of objects and events which form the basis for linking them together in a common group, for example, their perceptual or functional properties. The syntax of classification refers to the formal structure of the class thus constructed, for example, whether or not all of the class members share a common attribute. Developmental changes in the syntactic aspects—the "rules for grouping" as Kofsky (1963, p. 6) has called them—are the more interesting ones and will be described first.

The chapter by Olver and Hornsby just cited reports two studies of classification development. Since most of the major features of children's classificatory syntax reported elsewhere in the literature were also observed by these experimenters, their studies will be taken as the framework within which we discuss these features. Olver's procedure (see also Bruner and Olver, 1963) was to present a pair of words and ask how their referents were alike, then to present a third word and ask how all three were alike, then a fourth, and so on, through a list of eight. One of her lists included the words *banana*, *peach*, *potato*, *meat*, *milk*, *water*, *air*, and *germs*, for example. Her Ss were 6 to 18

years of age Hornsby's procedure was closer to that of the traditional sorting test. Children of 6 to 11 years were presented with an array of 42 water-color pictures of familiar objects (apple, clock, umbrella, etc.). S was first asked to select from the array a group of pictures that were alike in some way, "any way at all in which a group of things is the same." After the child had completed his grouping, he was asked to tell how the pictures selected were alike, the pictures were returned to the array, and the child was then asked to form another group, and so on, through 10 sorting trials.

The classificatory behavior of the Ss in both studies was categorized under three main rubrics in terms of class structure or syntax.

1 *Superordinate groupings* This is the familiar logical-classification grouping all the objects in the class share one or more common attribute (e.g., banana, peach, and potato are "all food" or "all have skins"). As would be expected, there was a convergence with age toward the exclusive use of this grouping strategy in both studies.

2 *Complexive groupings* These structures are not so easily characterized, as their name implies. There also appear to be a number of semidistinguishable subvarieties, but we shall not describe each one individually here (Bruner, Olver, and Greenfield, 1966, Chap. 3, Bruner and Olver, 1963). In general, complexive groupings appear to be the result of a conventional find-the-common-attributes strategy which the child fails, for any of a number of reasons, to carry off for the whole set of objects to be grouped. The child might, for instance, find a perfectly acceptable similarity between two of five objects in his group, but then find no similarity, a nonsimilarity (a contrast), or a different similarity for the remaining three. Or, alternatively, he might select one of the objects and treat it as a common property shared by all the rest. Bruner and his colleagues refer to this kind of complex as a "key ring", for instance, *germs* function as the "ring" in the rationale, "Germs are in banana, peach, potato, meat, milk, water, and air." Whatever the particular form of the complex, it represents an *inconsistent* class (Kofsky, 1963) in the sense that not all the objects are taken as belonging to the class on the same basis, for the same reason (i.e.,

common attributes). Hornsby's data also give evidence of something like the complement of inconsistency, Kofsky refers to it as *nonexhaustiveness*. As in the complexive grouping, the child attempts to use equivalence or similarity relations to form his class, but he fails to include in his group all the objects that possess the property he has chosen as his criterion for class membership.

The young child will form a group consisting of *house* and *barn* "because they have red on them," and yet ignore the red *apple* and red *balloon*. Or he will select just two animals or two foods and fail to include the other animals or foods (Bruner, Olver, and Greenfield, 1966, p. 82).

In contrast to superordinate groupings, complexive groupings and allied phenomena show a definite decrease with age in both studies.

3 *Thematic groupings* The less ambitious of Olver and Hornsby's complexive groupings come perilously close to ignoring the similarity or common-attribute constraints of the classification task altogether (e.g., "Bell is black, horn is brown, telephone is blue, radio is red"). Then thematic groupings systematically ignore them. The elements of the group are interrelated, but the relations are not those of equivalence or similarity. Rather, they are linked together, with greater or lesser ingenuity and logic, in some sort of story or theme, for example, "The little boy was eating a banana on the way to the store to buy some peaches and potatoes." Unlike both superordinate and complexive groupings, the link between items is not of the common-attribute variety, and unlike superordinate but like complexive groupings, the same link does not hold between all pairs of items. They could therefore be thought of not only as nonclasses but also as inconsistent nonclasses. Thematic groupings were virtually absent in Olver's protocols but were rather commonly seen in Hornsby's, like complexive groupings, they showed a clear decline with age.

As indicated, much of the developmental story on classificatory syntax can be derived from these two studies alone, the numerous other investigations in the literature mostly reinforce their conclusions and, in some instances, provide the basis for further con-

ceptual elaboration of them. Let us begin with the thematic groupings. Formally speaking, they bear a striking resemblance to the configurations or patterns created by Ricciuti's 40-month-olds (Ricciuti and Johnson, 1965). In both cases, common properties are eschewed in favor of common participation in some totality. If the items to be grouped are meaningful ones, as in Hornsby's task, the totality is likely to be a theme or story. If they are relatively nonmeaningful, as in Ricciuti's and Inhelder and Piaget's (1964) tasks, it will tend to be a design, pattern, or constructed object of the jigsaw puzzle type. In either case, the result is not a class, as the complexive grouping strives to be and the superordinate grouping succeeds in being, but simply a structured whole. Correspondingly, the relation between item and totality is one of part to whole rather than class member to class (Inhelder and Piaget, 1964).

Inhelder and Piaget have done the most extensive work on preclasses of the Ricciuti variety, which they refer to as *graphic* (or *figural*) *collections*. These collections were frequently found in their 2½- to 5-year-olds. Recall that Ricciuti's 3-year-olds did both classlike and configurationlike sorting (Ricciuti and Johnson, 1965). Inhelder and Piaget's graphic collections often showed evidence of both sorting tendencies. In a typical graphic collection, the child might begin by putting similar objects together and then add dissimilar ones to them, perhaps ending up with a meaningful structured whole (e.g., a jigsaw puzzle-like "house"). Some of Hornsby's examples of thematic groupings also look like admixtures of classes and nonclass wholes, in general, one would expect to find numerous transition structures between the thematic grouping or graphic collection and the complexive grouping. For an interesting analysis and interpretation of young children's graphic collections, see Inhelder and Piaget (1964, Flavell, 1963a, pp. 304-306). Many other studies, utilizing a variety of procedures, confirm the young child's predilection for graphic collections and thematic groupings (Annett, 1959, Goldman and Levine, 1963, Lovell, Mitchell, and Everett, 1962, Reichard, Schneider, and Rapaport, 1944, Sigel, 1953, Szeminska, 1965, Thompson, 1941, Vygotsky, 1962, Weigl, 1941).

There is also considerable supporting evi-

dence for Olver and Hornsby's observations regarding complexive and related classificatory behavior. It was Vygotsky (1962, Chap. 5) who originally used the term "complex" in the early thirties, and the varieties he described are very similar to those reported by these authors. As indicated earlier, children's classification efforts at the level of the complexive grouping characteristically fail to satisfy the dual requirements of *consistency* (all members of the group share the same common property or properties) and *exhaustiveness* (all objects sharing the property or properties are included in the group). The frequent failure of young children to observe the consistency constraint has been noted by Annett (1958), Goldman and Levine (1963), Lovell, Mitchell, and Everett (1962), Thompson (1941), Vygotsky (1962), and Werner and Kaplan (1950). The child's failure to establish exhaustive classes in free-sorting tasks seems in part to be the consequence of a tendency to form two- and three-object groups (recall the preceding quotation from Bruner, Olver, and Greenfield, 1966). This tendency, nonexhaustive sorting, or the two in combination have also been reported in several studies (Annett, 1959, Goldman and Levine, 1963, Kofsky, 1966, Reichard, Schneider, and Rapaport, 1944, Szeminska, 1965).

There are other observations about children's classification below the level of the superordinate grouping that should be mentioned. Not surprisingly, the developmental level of the child's groupings is usually higher than that of his verbal definitions or explanations regarding them (Reichard, Schneider, and Rapaport, 1944, Saarinen, 1964, Vygotsky, 1962). Szeminska (1965) and Inhelder and Piaget (1964) have stressed the lack of planning and self-monitoring in the young child's classificatory activity. "If we try to analyse the course of behaviour and thinking at stage I [the stage of graphic connections], we are inevitably struck by the fact that the child is taking each step as he comes to it, forgetting what went before, and not foreseeing what must follow" (Inhelder and Piaget, 1964, p. 285). It is apparent that a systematic absence of foresight and hindsight would alone be sufficient to produce a nonsuperordinate end result. The young child's categories have also been characterized as fluid and unstable, subject to abolition or redefinition

from moment to moment as conditions change (Kofsky, 1963, Vygotsky, 1962, Werner and Kaplan, 1950) Kofsky (1963, 1966) has devised an ingenious procedure for tapping one aspect of class stability. Her "conservation of class" task (analogous to the Piagetian tests for conservation of number, length, etc) probes the child's understanding that members of a given class continue to retain their class-membership status even when separated from each other spatially. And, finally, Bruner and Olver (1963) epitomize much of what is known about children's classificatory syntax in suggesting that development here consists largely of

the growth of strategies of grouping that encode information in a manner (a) that chunks information in *simpler* form, (b) that gains *connectedness* with rules of grouping already formed, and (c) that is designed to *maximize the possibility of combinatorial operations* such that groupings already formed can be combined and detached from other forms of grouping. In a word then, what distinguishes the young child from the older child is the fact that the younger one is more complicated than the older one, not the reverse (p. 134)

Developmental changes in the semantic aspects of classificatory behavior are less clear cut, both factually and in terms of their probable significance for an understanding of cognitive growth. Generally speaking, there appears to be an ontogenetic shift—clearly evident in one study, less so in another—from equivalences based on the more concrete and immediately given perceptual, situational, and functional attributes of objects to equivalences of a more abstract, verbal-conceptual sort, in particular the use of class names ("animals," "fruit," etc) as the basis for grouping. The relevant evidence is to be found in both the sorting and classification literature (Annett, 1959, Bruner and Olver, 1963, Bruner, Olver, and Greenfield, 1966, Goldman and Levine, 1963, Natadze, 1961, Reichard, Schneider, and Rapaport, 1944, Rucciuti, 1966a, 1966b, Sigel, 1953, 1954, Szeminska, 1965, Thompson, 1941) and in studies of children's vocabulary-definition preferences (Feifel and Loige, 1950, Kluglov, 1953, Russell and Saadeh, 1962, Wolman

and Barker, 1965). Moreover, in tasks where all the available equivalence options are perceptual, there is a subsidiary research corpus of ancient lineage which reports developmental changes in the saliency of such attributes as the gradual dominance of form over color cues with increasing age. For good recent studies of this genre, see Corah (1966), Lee (1965), and Suchman and Trabasso (1966a, 1966b).

The evidence also strongly suggests that the property an individual will single out as the basis for linking objects together will depend upon factors in addition to his developmental status. It will depend upon the possibilities afforded by the available objects (the Olver and Hornsby studies, for instance, show this to be an extremely powerful determinant), upon the individual's style of conceptualization (e.g., Kagan, Moss, and Sigel, 1963), possibly upon the wording of the sorting instructions (the use of "belong together" versus "are alike in some way"), and other variables.

Classes in Interaction Piaget and Inhelder have been the chief contributors to our developmental knowledge in this area (Piaget, 1952, Inhelder and Piaget, 1964, see also Flavell, 1963a, pp. 190-193, 306-309). The ontogenetic target here is an individual who understands and can think in terms of certain basic facts and rules concerning the interactions among classes. These include the recognition that a set of objects may be members of a number of classes simultaneously and a grasp of the exact quantitative relations holding among the extensions (i.e., the set of objects comprising the class members) of these classes. If the extensions of two classes overlap (i.e., there exist objects which are members of both), an understanding of this overlap can be described as a tacit understanding of class multiplication. For instance, the (logical) multiplication of the classes "Republicans" and "New Yorkers" yields the product class "Republican New Yorkers"—precisely those individuals who belong to both of these classes at once. The intersection of two classes may leave a nonintersecting remainder in both classes, as in the example just given (New Yorkers who are not Republican, and Republicans who are not New Yorkers). On the other hand, one of the classes may be wholly included within the other, with only

the latter possessing a nonintersecting remainder. For example, all terriers are dogs but there are also dogs that are not terriers. An individual who grasps the structure of this or similar classification paradigms understands something of class addition as well as class multiplication. He not only can multiply the classes "dog" and "terrier" and get the class product "terrier," but he also can add (logically) "terrier" and "nonterrier dog" to get the sum or superordinate class "dog" ("Republicans" and "New Yorkers" can also be added in the same way, of course, but that fact is not germane to the present discussion).

The research of the Geneva group has been largely directed at studying the child's growing skill and knowledge regarding these and related properties of class systems. Inhelder and Piaget (1964) report a variety of experiments which suggest that young children have great difficulty with problems demanding an understanding of multiple class membership and class multiplication. Once they have imposed a classificatory division on a set of objects, for example, they find it difficult to reclassify these same objects on some other basis. In another of their studies, S is presented with a horizontal row of pictures of different colored *leaves*, which forms an L with a vertical row of pictures of diverse *green* objects. S's problem is to decide which picture should go in a blank space that lies at the juncture of the two series. The older Ss (about 9 to 10 years) quickly sense the class-intersect character of the problem and insert a picture of a *green leaf* in the blank space, whereas the younger ones characteristically choose a depicted object which belongs to only one of the two classes (e.g., another leaf of any color).

The young child's problems with class addition and related operations are illustrated by a more celebrated series of studies (Piaget, 1952; Inhelder and Piaget, 1964). These studies show that, whereas the young child has no difficulty in recognizing that a set of, say, ducks and nonduck birds together comprise a collection of birds, he is systematically incapable of correctly answering E's query as to whether there are more ducks or more birds in the set. The child's problem here is said to involve an inability simultaneously to hold in mind superordinate and subordinate classes, in order to compare their extensions

Inhelder and Piaget (1964) also describe a number of other experimental probes into the child's understanding of superordinate-subordinate class relationship, for example, investigations of his growing ability to manipulate the quantifiers "some" and "all" with reference to the extensions of classes thus related. According to Piaget, the child gradually masters the basic rules and operations governing the interaction among classes during the early to middle elementary school years, and this mastery is interpreted in terms of the acquisition of concrete-operational structures.

There have been a number of attempts to replicate or extend Inhelder and Piaget's findings (Dodwell, 1962; Elkind, 1961c; Hood, 1962; Hyde, 1959; Kofsky, 1966; Lovell, Mitchell, and Everett, 1962; Morf, 1959; Sigel, Saltz, and Roskind, 1967; Wohlwill and Katz, 1967). In general, these investigators find roughly the same developmental phenomena that Inhelder and Piaget found, with perhaps a difference in detail here and there. The young child's difficulty with the class-inclusion problem (more ducks or more birds?), for example, has been repeatedly reconfirmed. There are other, nonreplication studies which also give corroborative information. For instance, the young child's relative inability to shift criteria and reclassify the same set of items in different ways is well documented (Heald and Marzolf, 1954; Reichard, Schneider, and Rapaport, 1944; Saarienen, 1964; Thompson, 1941). The classic papers by Welch and Long on the learning of class hierarchies should perhaps also be cited here (Welch, 1940; Welch and Long, 1940a, 1940b), although the writer has found it very difficult to interpret and evaluate these particular studies. Finally, there is an interesting study by Mosher which illustrates how the child's growing expertise with class hierarchies gets expressed in the information-seeking strategies he uses when playing the game of Twenty Questions (Bruner, Olver, and Greenfield, 1966, Chap. 4).

Conclusions This discussion began with a distinction between classes as intellectual instrument and classes as intellectual object. What is to be learned from the literature just reviewed about the development of each of these? For classes as intellectual instrument, the answer is uncertain. There is still no convincing reason to suppose that an individual's

behavior on a sorting task is a really faithful reflection of the spontaneous categorizations he makes in everyday situations. In particular, we suspect with Brown (1965, p. 328) that the typical adult utilizes categories of a wider genetic range in everyday life than you would be led to believe from the neat superordinate groupings he gives you on your sorting test. The problem is partly that we really are not sure what stimulus properties such tests have for Ss of various ages—just what implicit self-instructions the materials and formal instructions arouse in S.

For classes as intellectual object, the answer is a bit clearer, although some of the same interpretative problems apply here as well. The literature suggests that the child in our culture gradually acquires a functional command of the rules and regularities which obtain in the isolated class and in systems of interrelated classes. One can only assume that this growing understanding has important effects upon the categories the individual habitually uses, and especially upon the way he uses them in everyday reasoning and problem-solving situations.

Relations

The conceptual link between relations and classes is obviously a very close one. For instance, equivalence, difference, conjunction, disjunction, and other relations continually figure in our assignment of objects to classes. It is no surprise, then, to discover numerous parallels between the development of relational and classificatory thinking. First, the distinction between intellectual-instrument and intellectual-object aspects applies here as it did to classes. The child can be said to acquire a repertory of particular kinds of relations which he imposes on data, and he can also be said to acquire an understanding of the properties of relations in general. Second, relational thinking, like classificatory thinking, appears to have its origins in the sensorimotor period of infancy (Inhelder and Piaget, 1964, p. 13), although the relational equivalent of Ricciuti's (1965) study on early classification behavior has apparently not been done yet. Third, it is again possible to divide the developmental evidence according to its bearing on relations taken in isolation or in interaction with one another: the child learns what a relation is, and he also learns about *systems*

of relations. Moreover, Piaget's theoretical analysis has shown that systems of relations, like those of classes, are susceptible to the operations of logical addition and multiplication. In fact, of the eight concrete-operational groupings he uses as models for middle-childhood cognitive attainments, the most important are said to be the four dealing with the addition and multiplication of classes and relations (Inhelder and Piaget, 1964, p. 278). And finally, implied in what has just been said, the developmental mastery of the fundamental properties of relations and of classes appears to be roughly synchronous, that is, both are attained during the elementary school years.

Relations in Isolation. One way to approach this topic would be to chronicle the developmental acquisition of particular individual relations, taken in their intellectual-instrument aspect. For instance, Kleezer and Dallenbach (1929) and Robmowitz (1956) have shown that it is not until age 6 to 7 years or so that the child seems to have acquired the relation "opposite of." Similarly, there are many studies in the literature on children's learning concerning the age at which relational concepts such as "middle-sized" enter the child's functional repertoire. It might, however, be more illuminating (and would certainly be less space-consuming) to restrict our attention to the intellectual-object side of the problem, that is, to the child's progressive understanding of what a relation—any relation—is and implies. This also involves looking at the child's reactions to specific relational concepts, but with an eye to drawing more general conclusions.

The pertinent observations appear to have been made first by Piaget some years ago (Piaget, 1928, Chap. 2-3; Flavell, 1963a, pp. 276-278). His principal finding was that young children tend to misconstrue relations as absolute classes; this is true for both symmetrical relations (e.g., "brother of") and asymmetrical relations (e.g., "left of," "darker"). Such expressions are taken simply as class names for sets of objects sharing some common property rather than as relations holding between objects. Thus the relative, "darker," is interpreted as the absolute, "dark," and "brother" is at first simply "a boy." Furthermore, because the child is insensitive to the relational connotations of

terms like "brother," he fails to realize that he himself is also a brother of his brother, that is, the reciprocal nature of such symmetrical relations escapes him. Piaget summarizes the young child's conception of relations as follows:

The conclusion to which we are finally led is this. The child does not realize that certain ideas, even such as are obviously relative for an adult are relations between at least two terms. Thus he does not realize that a brother must necessarily be the brother of somebody, that an object must necessarily be to the right or left of somebody, or that a part must necessarily be part of a whole, but thinks of all these notions as existing in themselves, absolutely (1928, p. 131)

Piaget attributes the young child's difficulty in grasping the relativity of relations to his cognitive egocentrism, defined as a generalized inability to envisage multiple perspectives or points of view, that is, to see things relatively rather than absolutistically. It is worth noting that something like this confounding of relations with classes was also detectable in the child's early classificatory activity, where objects are frequently grouped together on the basis of various (nonequivalence) relations holding between one object and another, thus giving rise to thematic groupings and graphic collections. Piaget's findings regarding the developmental aspects of relations in isolation have been substantially confirmed by other researchers (Danziger, 1957; Elkind, 1961e, 1962a).

Relations in Interaction We have already said that the operations by which sets of classes can be interconnected have their analogues in the domain of relations. As in the section on classes, our description of these operations will be incomplete and nonrigorous, intended only to illustrate some basic points (Flavell, 1963a, Chap. 5). First, roughly parallel to the imposition of a class hierarchy on an object domain is the operation of serializing a set of objects, for instance, lining up a set of sticks in regular order from shortest to longest. The relations between the objects so serialized are then susceptible to a kind of logical addition, analogous to the addition of classes. For example, if the ordered series is represented as $A < B < C < D$ (A shorter than

B , B shorter than C , etc.), then the relation ($A < B$) "plus" the relation ($B < C$) "equals" the relation ($A < C$), the addition of relations thus expresses the transitivity of these relations. The same would be true for certain symmetrical relations, such as "equals" or "is brother to." $A = B$ "plus" $B = C$ "equals" $A = C$, if A and B are brothers, and B and C are brothers, then so also must A and C be brothers. Furthermore, relations can be multiplied as well as added. Given a square matrix embodying two serializations in which, say, the objects become increasingly darker in color as one moves along the rows from left to right, and increasingly larger as one proceeds down the columns, some object X in the matrix can be conjunctively characterized as at once darker *and* larger than some Y , lighter *and* equal in size to some Z , etc. A product relation like "darker and larger" is thus the counterpart of a product class like "New York (and) Republican."

We can now define some developmental objectives regarding a basic understanding of relations in interaction. The child will need to acquire the ability to serialize correctly a potentially orderable but unordered collection of objects, and to understand clearly that the n th object in his constructed series occupies that position because it is at once larger, say, than object $n - 1$ and smaller than object $n + 1$. Given this ability and understanding, the interpolation of new and additional objects into the series will pose no problem, since the $[(n - 1) < n < (n + 1)]$ "rule" will guarantee the correct placement of each object. The child will also need to grasp the transitivity principle implied in the serial addition operation. He should eventually be able to regard the conclusion $A < C$ (or $A = C$) as logically necessary, given only the information $A < B$ and $B < C$ (or $A = B$ and $B = C$), regardless of countervailing suggestion from E or from the perceptual properties of A , B , and C themselves. Finally, he should acquire the same sensitivity to the multiplicative possibilities of sets of different relations that he does for sets of different classes (recall Inhelder and Piaget's experiment on the intersection of green objects and leaves), and he should also be able to reason in terms of product relations on problems where such reasoning might be helpful.

Piaget has analyzed the developmental

problem of relational systems in roughly the manner just described, and he has conducted his research accordingly. First, he has shown that young children have real difficulties in arranging unordered objects into an ordered series and, when first able to do this, cannot continue to insert new items into it correctly (Piaget, 1952, Chap. 6, Inhelder and Piaget, 1964, Chap. 9).

Similarly, the empirical establishment of a relation between A and B and between B and C does not initially suffice for definite conclusions regarding the relation between A and C . This absence of transitive inference has been found to characterize the young child's reasoning with respect to both asymmetrical (Piaget and Inhelder, 1941, Chap. 10) and symmetrical (*ibid.*, Chap. 11) relations. For instance, given three objects of varying sizes and colors of identical or different weights, the child will not reliably and with subjective certainty conclude that $A = C$ on the basis of $A = B$ and $B = C$, or that $A < C$ on the basis of $A < B$ and $B < C$.

Moreover, the multiplication of relations also appears to be an operation foreign to the young mind. In one of these studies, Inhelder and Piaget (1964, Chap. 10) gave children of different ages 49 cut-out pictures of leaves orderable both by size (7 sizes) and by shade of color (7 shades) and probed in various ways for their ability to construct the 7×7 matrix. The youngest Ss failed to seriate at all. Older ones could construct one of the series or sometimes both in succession, but without being able to effect a multiplicative synthesis of the two. After the age of 7 or so, partial or complete matrix-building became quite common. One gets the impression from reading Inhelder and Piaget's behavior records here (1964, p. 275) that these oldest Ss "knew what the game was" in a way that the younger ones did not. It should also be mentioned that Piaget assigns a very important and general mediative role to the child's growing ability to multiply relations; it is said to be a developmental bridge to the attainment of the various conservation concepts (e.g., Piaget, 1952, Chap. 1).

There have been a number of independent confirmations of Piaget's assertions regarding early difficulties in constructing series and in interpolating new elements into already-constructed ones (e.g., Chittenden, 1964, Elkind,

1964a, Lovell, Mitchell, and Everett, 1962). In addition, there are many studies on number development which support these assertions in a less direct manner (see the next section).

There can also be no doubt that a grasp of the transitivity rule develops with age (Chittenden, 1964, Hood, 1962, Hyde, 1959, Lovell and Ogilvie, 1961b, Youniss and Furth, 1965, 1966, and numerous other studies to be cited in later sections). The two experiments by Youniss and Furth are particularly interesting. In the earlier one (1965), children of grades K, 1, and 3 were required to learn arbitrary causal sequences, namely, which of three balls (identical in size but different colors) would push one another off an inclined plane. They found that the older groups, but not the younger one, learned a given sequence significantly faster if it embodied the transitivity principle (A pushes B off the plane, B pushes C , and A pushes C) than if it did not (A pushes B , B pushes C , but C pushes A). In the second study (1966) they found that kindergarten children learned transitive sequences more easily than intransitive ones only when the perceptual cues were congruent with the sequence (i.e., bigger balls pushing smaller ones), first- and third-graders, on the other hand, learned transitive sequences more easily regardless of the congruency-incongruency of these cues.

There is less evidence regarding the development of relational multiplication, but what there is confirms the Geneva findings (Bruner, Olver, and Greenfield, 1966, Chap. 7, Lovell, Mitchell, and Everett, 1962). Lovell, Mitchell, and Everett essentially repeated Inhelder and Piaget's original procedure and obtained similar developmental trends. Bruner and Kenney (Bruner, Olver, and Greenfield, 1966, Chap. 7) were more innovative. They presented children with a square matrix of nine beakers, the beakers increasing in height along one axis and in width along the other. The Ss were tested both for their ability to reproduce the original matrix from memory and for their ability to complete a transposed matrix which E began for them by moving the shortest and thinnest glass from its original position in the southwest corner of the matrix to the southeast corner. The results were dramatic. Whereas 5% of the 5-year-olds could reproduce the original matrix, not one

could complete the transposed version. In contrast, 4% of the 7-year-olds succeeded on both tasks. It would be a fair interpretation of their data to say that the older child understands the multiplication-of-relations principle implicit in the arrangement of the glasses and therefore can transpose as easily as he can reproduce, this principle eludes the younger child, and hence he sees only a specific and immutable spatial configuration.

Number

We now consider normative-descriptive research dealing principally with the child's developing grasp of certain very basic and important properties of number and the number system. Developmental investigations of other mathematical concepts such as the concept of probability will be taken up in the next section.

Virtually everything of interest that we know about the early growth of number concepts grows out of Piaget's pioneer work in the area (Piaget, 1952; Churchill, 1961; Flavell, 1963a, pp. 309-316). Piaget saw early that revealing studies here must focus on tacit mathematical assumptions and beliefs which may be considerably removed from the child's overt behavior with respect to the number system, that is, they must deal with the genotypes rather than the phenotypes of mathematical behavior. He argued that what the child really understands about the nature of number cannot be reliably inferred from the conventional numerical operations (counting, adding, etc.) he is called upon to learn and perform in the traditional classroom; instead, new and radically different methods must be devised to probe for this understanding—for the child's number *concepts* in the true sense of the word. Although such an approach would probably elicit a condescending "of course" from today's educator or developmental psychologist, it is important to realize that it did not always seem self-evident. Consider the following excerpt from a 1942 book, *The Early Development of Number Concepts*. A test was given to some 1290 children just entering elementary school in order to find out what they already knew about arithmetic. The nature and rationale of this test are apparent from the author's conclusions:

It is obvious that whereas almost all pupils

entering school can perform rote counting by units, only about 20 per cent can accomplish rote counting by tens, and the number who succeed in counting backwards is negligible. Practically all children entering school are competent to some degree in rational counting, and more than half succeed in actual counting up to 10 or 15. Over 90 per cent of school entrants can give 2 objects, over 50 per cent can give 5 objects, and over 20 per cent can give 10 objects when they are required to do so by the teacher. The addition combination $1 + 2$ is known to almost half the pupils, and $3 + 1$ by a third, $2 + 3$ and $5 + 1$ are known to about 20 per cent. The subtraction combination $3 - 1$ is known to three-quarters of the pupils, whereas the corresponding addition combination $3 + 1$ is only known to a third, $5 - 2$ is as well known as $1 + 2$, and $7 - 3$ is known to a quarter of the pupils (Scottish Council for Research in Education, 1942, p. 27).

Piagetian research on number development can be divided for convenience of presentation into two parts. Piaget's original studies, carried out in the 1930s and first published in English in 1952 (Piaget, 1952), subsequent research on the problem, done primarily by Piaget's collaborators during the last 10 years. The original studies have become very well known to the psychological and educational public and have often been repeated by others. The recent work, as yet unrepeated (by non-Genevans) and untranslated, will undoubtedly be less familiar to most readers.

The Original Studies Piaget conceived the basic developmental problems in roughly the following way: What, exactly, are the essential cognitive components of an adequate elementary concept of number? That is, what must the child implicitly know about the properties of numbers in order to be credited with such a concept? Piaget believes that these cognitive components principally include a concrete-operational mastery of classification and seriation (the middle-childhood-level understanding of classes and relations described in the preceding two sections of this chapter). Number itself is actually conceptualized as a fusion or synthesis of classes and (asymmetrical) relations, according to a logical and epistemological analysis which will not be detailed here (see Flavell, 1963a, pp.

310-311 and the page references to Piaget, 1952, cited here) Because of the putative intimate relation among these three cognitive domains, several of Piaget's number-concept problems require for their solution the ability to classify and, especially, to seriate

In one of his tasks, for example (Piaget, 1952, Chap 5), the child is presented with two unordered but potentially orderable sets of 10 objects each—dolls of different heights and miniature walking sticks of different lengths. The child is told to arrange the dolls and sticks in such a way that each doll can easily find the stick that belongs to it. The solution is to seriate the objects in each set and bring the appropriate doll-stick pairs together, in optical correspondence, for instance, the fourth-largest doll must be placed opposite the fourth-largest stick. Once this is accomplished, *E* closes up one of the series so that each stick is no longer directly opposite its owner, and *S* is asked to find the stick that belongs to some particular doll selected by *E*. The most interesting finding was that there were a number of children who could readily solve the initial, double-seriation part of the problem but could not find the correct stick for a given doll when the optical correspondence between the two series—each doll opposite its stick—was destroyed. In particular, the child at this stage was prone to confuse the *ordinal* number of the correct stick (n th) with the *cardinal* number ($n - 1$) of those smaller than it, thus often selecting the $(n - 1)$ th stick when the n th was called for. Several other of Piaget's studies (*ibid.*, Chap 6) also pointed up the pre-operational child's difficulties in differentiating and coordinating the ordinal and cardinal aspects of number—in terms of Piaget's initial conceptualization, its relational and classificatory components, respectively.

By all odds the most famous of Piaget's investigations in this area deal with the conservation of number. The tasks he used to elicit conservation or nonconservation responses in children varied from study to study, but one basic paradigm is used in all cases. Two sets of objects are established as numerically equivalent, usually by one-one correspondence rather than enumeration, for example, *E*'s row of objects and *S*'s row of objects are set in direct, one-one optical correspondence, as with the sticks and dolls, or

E puts a marble in one container every time *S* puts a marble in another container. The objects in the one set may have some natural connection with those in the other (e.g., dolls in the one set, their beds in the other), or they may not (e.g., a set of white beads versus a set of red beads), Piaget refers to the former as "provoked" and the latter as "spontaneous" correspondence (Piaget, 1952).

Whatever the specific form of the task, at some point conditions are so arranged that there is a lack of optical correspondence between the members of the two sets, with the result that the young child may experience what amounts to a perceptual illusion as regards the relative numerosity of the two sets. If the two sets had been placed initially in optical correspondence, say, two rows of equally spaced and opposing objects, *E* may destroy the correspondence by lengthening one of the rows, by transforming one row into a heap or a tower, or by effecting spatial subgroups within one of the sets (Piaget in this instance would speak of the "additive composition of numbers," i.e., the recognition that the sum of the subsets equals the total set). If the numerical equivalence had instead been initially constituted by one-for-one insertion of marbles into each of two identical transparent containers, *E* will have insured an eventual optical noncorrespondence by pouring the contents of one into a third, differently shaped container. The child is then asked whether the two sets now contain identical numbers or amounts of objects. The prototypical conserver steadfastly affirms their continued equivalence, the nonconserver denies it.

There is considerable controversy regarding just what characteristics of the child's structure account for conservation versus nonconservation responses, in the area of number and elsewhere, and especially regarding the mechanisms by which the former replaces the latter in the course of development. We shall touch on such questions later. There is no controversy at all, however, about the reality of certain gross differences between the two types of responders. The nonconserver is distinguished from the conserver both by what he does and by what he fails to do. What he does is treat the problem as a perceptual rather than a cognitive one, and in so doing he is likely to make a judgment of nonequiva-

lence on the basis of certain number-irrelevant cues such as length, width, and density. Thus the spread-out row is often said to contain more objects because "it is longer," the thin container because "it is higher" (i.e., the column of marbles is higher), etc. What he fails to do is draw logical conclusions from the fact that the two sets were initially established as equivalent by one-one correspondence (or by counting), and from the fact that the transformations which have been performed are not of the kinds that affect the numerosity of the sets. And what he does not have, quite obviously, is a coherent and differentiated—an "operational," as Piaget would put it—concept of number.

The claim that young children are systematically prone to nonconservation responses, in this and other areas, seems most improbable at first hearing, and it could have been predicted that subsequent researchers would leave no children untested in trying to support or falsify it. In the case of number conservation specifically, there is overwhelming evidence that the claim is indeed a valid one. We shall cite here only the replication-oriented studies of Piaget's conservation and other number-concept tasks; we defer to later sections consideration of investigations which verify the claim incidentally, while in the course of pursuing some other objective (attempts at training nonconservers to conserve, cross-cultural comparisons of the age at which conservation is attained, etc.).

Replications of one or more of Piaget's number-concept studies have been carried out by Almy, Chittenden, and Miller (1966), Beard (1963a), Dodwell (1960, 1961), Elkind (1964a), and Hood (1962). These investigators report essentially the same gamut of pre-operational and concrete-operational behaviors on the various tasks that Piaget found. The Almy, Chittenden, and Miller study provides especially strong confirmation in that it demonstrated progressive shifts from nonconservation to conservation responding in individual children, retested at 6-month intervals over a 2-year period (5 to 7 years of age).

It is unclear (at least to the writer) whether Piaget's theoretical analysis of the number concept as a synthesis of classificatory and relational operations actually ought to imply that the standard Piagetian tests for these

operations (e.g., seriation and class-inclusion tasks) should be negotiated earlier than, or in strict synchrony with, more direct tests of the number concept itself (e.g., tests of cardinal-ordinal correspondence or of number conservation). Whatever the logical status of this implication, its factual status is certainly very doubtful. Neither Piaget nor anyone else (e.g., Beard, 1963a, Dodwell, 1961a, Hood, 1962) has shown any convincing empirical evidence that seriation and classification tasks are regularly mastered prior to number tasks. Although there is some agreement across studies as to the order of difficulty among the various tasks, those assessing classificatory and relational operations are not uniformly easier than those assessing numerical ones.

Finally, there is a study by Gunderson (1955), which, although not conceived within a Piagetian framework, lends some support to his view that the elementary numerical operations become interconnected within a more general cognitive structure during early middle childhood. She found that second-grade children, already skilled in simple addition and subtraction operations, were surprisingly adept at solving simple multiplication and division problems, even though they had not yet received any formal instruction in these latter operations.

Recent Genevan Research. Inhelder and Piaget (1963) have done further studies of the child's developing ability to infer conservation of number from the repeated or recursive application of the operation of one-one correspondence. A variety of new tasks were employed (the Genevans seem to have an inexhaustible supply of techniques for assessing conservation concepts!), of which the following is prototypical. The child repeatedly performs the action of simultaneously adding a bead to each of two glasses, one wide and one narrow. At various points, *E* asks the child if the two sets of beads continue to be equal, covers the glasses with a cardboard box, has the child continue to drop marbles into the glasses through holes in the box, and then repeats the conservation question, asks if the sets would always continue to be equal if the child kept up the one-for-one process "all afternoon," or "for a long time." The child was further queried about each answer, as is usual in Piagetian research, and asked to justify his conclusions.

Two findings of this study are of particular interest. First, a number of the younger Ss were able to infer at any given point that the two sets continued to be equal, despite all appearances (the higher column of beads in the thinner glass), on the basis of their construction through the one-for-one operation. However, they were hesitant and uncertain about the equality after the cardboard boxes were added or when asked to extrapolate into the future. In contrast, one of the older Ss spoke for all concrete-operational thinkers in saying, "Oh yes, once you know, you know forever!" (*ibid.*, p. 66).¹ Second, operational-looking judgments and justifications seem to emerge earlier on this type of task than on the traditional number-conservation tasks, for example, where one of two identical glasses of beads is abruptly poured into another, different-shaped one. Inhelder and Piaget apparently construe these precocious successes as involving a primitive form of recursive reasoning, which will subsequently play a role in the formation of a concrete-operational conception of the number series.

An earlier study reported in Apostel, Mays, Moir, and Piaget (1957, Chap. 4) was concerned with the distinction between logically based and empirically based conservation judgments, a distinction implicitly present in the findings just described. Their task was the following: Two rows of buttons are set in one-one optical correspondence, and the child agrees that the rows are numerically equal. *E* then divides one of the rows into two or more clusters of buttons, for example, a row of eight may be rearranged into groups of 3, 3, and 2. A screen is placed between *S* and this row so that the child can see *E* create the subsets (and *E* also describes everything he is doing) but cannot actually count the buttons. The child then is asked if the two sets are still equal, and *E* tries to determine whether the child feels it necessary to remove the screen and count the buttons to be sure. As usual, it is the intermediary reactions that are of greatest interest. There appears to be a stage when the child is unwilling to either assert or deny conservation before counting; conservation has for him the status of an empirical hypothesis that has to be tested. Moreover, the less advanced children of this stage have to keep reconfirming the equality, always by counting, for each new division of the same set of

buttons. In addition, empirical verification through counting only leads to sure conservation judgments during this stage if the sets are relatively small (less than 15 or 20).

From this and other evidence, Piaget has elsewhere concluded that there is a *progressive arithmetization* of the number series in the course of development: numerical operations are at first constituted only for the domain of small, "familiar" sets, and they are then slowly extended over the entire series (Piaget, 1960, p. 65). On the other hand, the oldest Ss in the Apostel et al. sample (8 to 9 years) clearly regarded conservation as a logical necessity, given the nature of the transformation performed, and therefore disdained to count. As one of them said, "There's no need to count, it's just the same as it was before" (Apostel et al., 1957, p. 118).

The Genevans have explored still other variations of the conservation problem. Apostel et al. (1957, Chap. 5) describe a second task, also utilizing the screening procedure, in which symmetrical divisions are made in both rows of buttons. The top row may consist of 8 buttons subsequently partitioned into groups of 3 (left side) and 5 (right side), and the bottom row may consist of 8 buttons subsequently partitioned into groups of 5 (left side) and 3 (right side). The child's task is to judge whether a bar placed horizontally and vertically within the four-subset configuration will in each instance result in an equal number on either side of the bar. It does, of course

3	5	with the bar horizontal
5	3	
3	3	with the bar vertical
5	5	

As in the preceding study it was found that with increasing age the child feels increasingly less need to count in order to be sure of the equivalences. The most peculiar result, however, was that a number of the intermediate-stage Ss remained unconvinced that vertical bisection (which creates two *new* sets of two subsets each) resulted in numerical equality, even after counting!

Gréco (1962a) has also used a variation of the conservation procedure in an attempt to test the child's understanding of the commutativity law of addition: $x + y = y + x$. Two

rows of 8 equally spaced counters are placed in optical correspondence, one row directly above the other, the leftmost 5 in each row are white and the rightmost (remaining) 3 are red. The 3 red counters in the bottom row are slowly displaced, one by one, to the left of the white counters in that same row (thus effecting a spatial permutation of the whites and the reds), and the conservation question is posed. The developmental succession of responses to this task closely resembles that which is generally found in traditional conservation studies, on this and other grounds one is led to wonder whether the task really tapped anything more specific than conservation-nonconservation.

There is another, more interesting study by Gréco (1962b). He has shown that at least some children pass through a curious transitional stage before acquiring a clear-cut, adult grasp of number conservation. During this stage, the child clearly recognizes that the numerical labels of two sets remain invariant under number-invariant transformations (e.g., spreading out the objects in one of the rows), but he seems not to grasp the quantitative implications of this fact. That is, he will defend (often with operational-like arguments) the position that "there are still seven here and seven there", nevertheless, he will conclude that "there are more" in the longer row! Such a child is said to have acquired the conservation of *quotité*—of the numerical "names" which describe each set—but not yet the conservation of numerical *quantité* proper. Dodwell (1960) and Wohlwill and Lowe (1962) have noted a similar lack of integration between the absolute-numerical and relative-quantitative aspects of number in some of their young Ss.

Not all of the recent Geneva research in this area has dealt with number conservation. Moïf (1962), for example, has tried to study the child's growing understanding of the fact that numbers form a connected, unbroken series, for example, that in counting one by one from 2 to 10, you must necessarily "pass through," say, 7. He used several variations of the following technique. The child is initially presented with two sets of cubes: a set of 30, aligned on a wooden ruler, a set of 9 (set A) grouped together on the table. E tips the ruler so that one or two of the 30 slide off onto the table, thus forming the beginning

of a second group of cubes on the table (set B). E then asks "If I continue to make these blocks fall one by one, am I sure to end up having as many cubes on the left as on the right?" (i.e., must $B = A$ at some point as B continues to increase in size?). It is clear from Moïf's behavior records that some of the children were unsure of what would happen for largely artifactual reasons (e.g., they wondered if the sliding-off process could in practice be arrested at precisely the $A = B$ point). On the other hand, his records suggest that some of the younger children really were unsure that B would have to equal A in going from $B < A$ to $B > A$. He reports such responses as, "You're not sure—there could be one not enough and then one too many," and, "There could be more and afterwards less and never the same thing" (Moïf, 1962, p. 96).

The expression, "Given any number," is commonplace in mathematical arguments. Matalon (1963a, 1963b) and Gréco (1963a) have attempted to study the developmental acquisition of this concept of "any number" (*nombre quelconque*). Various techniques were used, all designed to probe for the insight that certain mathematical operations produce invariant results regardless of what numbers they are performed upon, and hence that the number in question need not be known or specified ("let n represent any given number"). It is intuitively obvious that this kind of mathematical understanding is more subtle and abstract than any so far dealt with in this section, and it is no surprise to find that most of Matalon's and Gréco's *quelconque* problems appear to require formal rather than concrete operations for their systematic solution.

In one of Matalon's (1963a) studies, the child was asked, in effect, whether $2n + 1$ will be divisible by 2 (i.e., will be an even or an odd number), whatever value of n is selected. The developmental trends found were not very pronounced, but there was at least some indication that the older Ss (near-adolescents) tended to be more sensitive to the generality of the answer—to the "no-matter-what-number-you-choose" character of the problem. In another study, two rows of white and red counters were set before the child in optical correspondence, each white opposite a red. E then mixed the two sets together and asked S

if the successive removal of randomly chosen pairs of counters from the pile would or would not leave a remainder. Some of the younger children were confident that pairwise depletion would leave no remainder, providing that each pair consisted of a red and a white counter, but were unsure for *paires quelconques*. The older ones recognized that any and all pairs were equivalent in this context.

Gréco's (1963a) tasks were too complex to be described here. In general, they also highlight the elementary school child's difficulties in seeing that all numbers can be regarded as equivalent for certain purposes of mathematical reasoning. In discussing these studies, Piaget speaks of a progressive *quelconquification* of numbers in the course of development, and he suggests that the child's increasing fluency with combinatorial operations plays a role in this process (Gréco, Inhelder, Matalon, and Piaget, 1963, pp. 13, 16). For other recent Genevan work on number concepts, see Vols. 11, 13, and 17 of Piaget's *Etudes d'épistémologie génétique* monograph series (published by Presses Universitaires de France).

Other Concepts

This brief section deals with a residual cluster of interrelated concepts of a logical-mathematical sort concerning which we have at least some developmental information. The principal one is the concept of chance or probability. Piaget and Inhelder (1951) have made an extensive theoretical and experimental analysis of its evolution, and there is also a small follow-up literature by non-Genevan researchers. Piaget and Inhelder have cogently argued that the full development of elementary probabilistic reasoning must await certain formal-operational acquisitions, namely, the concept of proportion and the ability to engage in combinatorial thinking. Some interesting developmental research has been done on proportions and combinations, however, and an initial examination of this research will serve as an introduction to the probability studies.

Combinations and Proportions In Piaget's theoretical system, combinatorial operations and an understanding of proportionality are characterized as *formal-operational schemas*—conceptual instruments or skills which are the developmental by-products of adolescent-level

thought organization in general (Piaget's group-lattice structure), and which can mediate the solution of a wide range of superficially dissimilar problems (Inhelder and Piaget, 1958, pp. 307-329; Flavell, 1963a, p. 222). Thus Piaget frequently appeals to the adolescent's underlying grasp of combinations and/or proportions to account for his ability to master many of the scientific-reasoning tasks he and Inhelder have given to this age group, such as problems involving the determination of the chemical properties of an array of identical-looking liquids, the discovery of the metrical regularities involved in the projection of shadows, and also—as we shall see—certain probability problems (Inhelder and Piaget, 1958; Piaget and Inhelder, 1951).

In the specific case of combinations, Piaget has made a more direct probe for the child's understanding (Piaget and Inhelder, 1951, Chap. 7). The child is presented with several sets of colored tokens, each set of a different color. His task is to form as many distinct, unlike-color pairs of tokens as he can. Given three sets of red, blue, and yellow tokens, for instance, the only possible unlike-color pairs would be red-blue, red-yellow, and blue-yellow. Piaget found that a sure and systematic procedure for identifying all the possible combinations was seldom in evidence before the age of 11 to 12 years, the beginning of the formal-operational period. Other studies (*ibid.*, Chap. 8, 9) showed that a similar management of permutation and arrangement problems is also largely an adolescent rather than middle-childhood achievement.

As for proportions, Lunzer (1965b) reports a sharp increase in the ability to master verbal and numerical analogies problems across the age period 9 to 11 years. These problems clearly have a relations-between-relations, proportional structure (e.g., "oval-sphere-round-ring-diameter is to circle as cube is to square"), and Lunzer argues that this fact explains the concrete-operational child's difficulty in coping with them.

Bruner and Kenney (Bruner, Olver, and Greenfield, 1966, Chap. 8) have done a particularly ingenious developmental study of this concept. Children of 5, 6, 7, 9, and 11 years were presented with pairs of glasses containing water, and asked to judge which glass is fuller and which glass emptier. The glasses in each pair varied systematically on a

number of dimensions their absolute height and diameter, the absolute height of their liquid column, the degree (proportion) to which they are full and empty. They found that younger children tend to judge solely on the basis of an undifferentiated estimate of the amount of water in the two glasses "fuller" or "full" means more or much water, "emptier" or "empty" means less or little water (the "much" or "little" often being indexed by the height of the liquid column without regard to its diameter). The 7- and 9-year-olds also tend to have an absolutistic conception of fullness and emptiness, but a more articulated one "fuller" means the glass with the most filled space and "emptier" the one with the most unfilled space. However, since the same glass may show *both* of these properties (e.g., the larger of two glasses, both half full), these children are susceptible to inconsistent and contradictory judgments, which the younger ones escape. And, finally, consistent with Piaget's and Lunzer's findings, there is a decided increase from 9 to 11 years of age in the number of judgments reflecting a proportional conception of these terms. Lovell (1961) has replicated a number of Inhelder and Piaget's probability and scientific-reasoning tasks, and his data also attest to the formal-operational status of combinatorial and proportional thinking.

Probability Piaget has proposed a theory concerning the ontogeny of probabilistic thinking (Piaget and Inhelder, 1951, pp. 226-250, Flavell, 1963a, pp. 341-347). It begins with an argument which the writer has summarized as follows:

In order to identify a set of phenomena as "chance events," one has first to identify a set of phenomena which are not chance events, a nonchance ground against which chance can emerge as figure. Only if cognitive processes are developed enough to order and organize the intrinsically certain, lawful, and predictable by means of rational operations, can things which are intrinsically uncertain, unlawful, and unpredictable be apprehended as such. Put most simply, a mind which knows no law can also know no lawlessness (Flavell, 1963a, pp. 341-342).

The pre-operational child lacks such operations and hence is generally unable to differ-

entiate clearly between the two realms, *a fortiori*, he cannot engage in genuine probabilistic thinking. The advent of concrete operations first makes such a differentiation possible, and during the latter part of this developmental period the child begins to train these operations on chance as well as nonchance events, in an attempt to extract whatever lawfulness and predictability he can. However, concrete-operational structures are essentially inadequate for most probability problems, and it is not until adolescence that his newly attained combinatorial and proportional schemas make possible any really systematic and effective treatment. Once given a systematic method for isolating all the possible combinations of a set of items, the child is in a position to understand the nature of random processes and to think about the chances of obtaining certain combinations from the total set of possible ones. Similarly, once endowed with a concept of proportionality, a genuine quantitative comparison of probabilities becomes possible. For example, only if such a concept is available can the child be sure that a collection of 2 red and 3 white marbles affords better odds for drawing a red than does a collection of 1 red and 2 whites, that is, that the proportion $\frac{2}{5}$ is greater than the proportion $\frac{1}{2}$.

Piaget and Inhelder (1951) used a number of different tasks to study ontogenetic changes in the child's understanding of probability (Flavell, 1963a, pp. 343-347). In one, an initially ordered arrangement of objects is progressively randomized, and *E* tries to assess *S*'s grasp of the randomization process. Other studies dealt with the child's ability to predict the kind of distribution (normal, rectangular) which would result from random movements of objects under various physical constraints, and with the child's reaction to the progressively more nonrandom-looking behavior of a crooked roulette wheel. The last series consisted of lot-drawing tasks, of which that discussed next is perhaps the most interesting (Piaget and Inhelder, 1951, Chap. 6).

Two logically equivalent variations on a set of probability-comparison problems were given to children of different ages. The stimuli were in all instances white tokens, some blank on both faces and some with a cross on one face. In the one variation, the child is shown two small collections of these tokens,

although those with the crosses are turned face down, *E* makes sure that *S* is fully informed of the composition of each collection (e.g., 1 cross and 3 plain in one, 2 crosses and 3 plain in the other). The child's task is to judge, in effect, which collection would more likely yield a cross on a random draw. In the other variation, only a single collection is used, and *S* must decide which *kind* of token (cross or plain) a random draw is more likely to produce. The composition of the two collections in this procedure was varied in ways designed to reveal the cognitive level of the *Ss*, for example, simple ratios of 1/2 and 2/2 (for the two collections) versus more difficult ratios of 1/3 and 2/6, or of 1/2 and 2/3.

An analysis of *Ss*' responses to the various subtasks suggested the following developmental sequence (ages approximate, of course). The youngest children (4 to 7 years) either entirely fail to respond in terms of the quantitative relations involved, or can occasionally do so on an intuitive basis when the perceptual proportions are particularly striking. Beginning at about 7 years of age, regular and systematic solutions to certain classes of tasks become manifest. In the case of the single-collection problem, the child now invariably selects the kind of token that is numerically superior, in the case of the two-collection problem, he analogously chooses the collection which has the most crosses in it. What he is still unable to do, as would be predictable from the proportion-concept studies reviewed previously, is to judge on the basis of the *proportion* of crosses-to-total, as opposed to the *absolute number* of crosses, in each of the two collections. For instance, he is inclined to think that 2/4 presents better odds than 1/2 simply because there are more crosses in the first collection. Toward age 11 (i.e., the end of Piaget's concrete-operational period) the child begins to reason in terms of the proportions in play, and he does so systematically in the years following. Here is an example of the kind of transitional thinking Piaget encountered in some of his *Ss*. The problem is the one just mentioned and the child is 9 years of age.

Here (2/4) No, it's there (1/2), because there is only one without a cross (Why did you say the other one?) Because there are two crosses (Well, which counts the most, two

crosses or one without a cross?) One without a cross, two crosses it's the same, because there are two crosses and two without crosses (in 2/4) (Then one of the two is easier?) No, it's the same, but it's sure! here (2/4) because there are two crosses (very perplexed) (Piaget and Inhelder 1951, p 166)

In a related study (*ibid*, Chap 5), the child's task is to predict the likeliest draw (of either one or a pair of tokens) from a bag containing different numbers of tokens of several colors (e.g., 15 yellows, 10 reds, 7 greens, and 3 blues). Where the draw of only a single token is to be predicted, this task of course becomes a simple variant of the one-collection problem just described. Once again, the authors argue from their data that pre-operational children are largely incapable of assessing comparative probabilities.

There are three experiments by American psychologists which take the Piagetian lot-drawing procedures as their point of departure (Yost, Siegel, and Andrews, 1962, Davies, 1965, and Goldberg, 1966). Although the procedures and results of these three experiments of course differ from one another on a number of points, there are enough similarities to permit the following single statement of their collective message.

Probabilistic thinking undoubtedly undergoes developmental changes, as Piaget and Inhelder had claimed (the Davies study was in fact partly normative-developmental in design). However, at least the beginnings of this development occur earlier than Piaget and Inhelder would have us believe. There are a number of "noisy" variables in the Piaget and Inhelder procedures, features which may impede the behavioral actualization of what the child really knows about probability. If one uses a testing method designed to eliminate or neutralize such variables (e.g., a method that relies less heavily on the child's verbal skills, controls for his initial stimulus preferences, and provides better memory aids for the composition of the collections), it can be demonstrated that more young children will behave in accordance with the event probabilities than will be the case with Piaget and Inhelder's original methods.

All three of these experiments appear to have been carefully designed and executed, and the writer is not inclined to doubt their

findings as such. The interpretation of these findings is quite another matter, however. As will be seen, there are now numerous studies in the Piagetian literature attempting to show that some given operation enters the child's repertoire earlier than Piaget had claimed. The problem which such studies bring forcibly to our attention is the very difficult and involved one of defining, both conceptually and operationally, precisely what is meant by "having" an item in one's cognitive system. If there could be agreement on just what it means to have "attained" any item, and on the exact test behavior that distinguishes attainment from nonattainment, the dating of cognitive acquisitions would be an easy matter. But there is no such agreement in the field at the present time, in fact, the problem itself has not yet attracted the serious attention it deserves. As in the case of the term "concept" itself, the difficulty is of course not in finding *some* definition (and *some* associated test criterion) but in finding a *principled, theoretically based* one—in effect, a revealing and heuristic way of conceptualizing the question. A later section of this chapter is devoted to this and related matters (Developmental Diagnosis of Conceptual Acquisitions). In the present case, it can at least be said that there is little in the data of the aforementioned three investigations that would lead one to conclude that the pre-operational child really "has"—to invoke that vague word again—very much in the way of probabilistic-thinking skills (Goldberg, 1966, Conclusions).

As already indicated, these three studies suggest that the growth period for probabilistic reasoning should be extended further toward the birth end of the ontogenetic span than Piaget would have it. To balance matters, there are three other studies which suggest that the typical level of functioning at the other end of this period may be lower than he supposed. Teachers of statistics will not be surprised to learn, for example, that untutored adults have been found to show rather poor intuitions about the concept of correlation (Smedslund, 1963d). Similarly, Ross has demonstrated that the reasoning of adolescents and adults in chance situations is likely to show nonprobabilistic as well as probabilistic features (Ross, 1966, Ross and Levy, 1958). He found, for instance, that the "gambler's fallacy" (exemplified in the belief that

a head becomes ever more probable, in a coin-tossing situation, as a run of tails grows longer) actually *increases* in frequency with age during the adolescent period. Piaget is probably right in believing that, as the child develops, he becomes increasingly able and disposed to train intellectual operations on probabilistic problems. Not all of these operations need conform to the tenets of probability theory, however, and a good number of them—for example, those that underlie gambler's-fallacy predictions—probably will not. As the Bruner and Kenney study so neatly illustrates (Bruner, Olver, and Greenfield, 1966, Chap. 8), intellectual development makes possible not only new truth, but also new and more exotic forms of error.

THE NATURAL WORLD

Objects

Some 40 years ago Piaget made an intensive and careful study of the sensorimotor development of his own three children. Most of what he discovered in this work is of significance for a treatment of concept development, but his findings regarding the infant's changing conception of objects (the so-called "object concept") deserve particular attention (Piaget, 1954, see also Flavell, 1963a, pp. 129–135, and Gounin-Décaille, 1965, Chap. 2). According to Piaget, during the period of infancy the child gradually and step by step makes an ontological discovery of enormous significance for his subsequent development: the objects that populate his world maintain a permanent existence and physical integrity independent of his own intermittent sensory and motor contacts with them. The child "has" such a concept, in other words, to the extent that he tacitly assumes that objects are no less in continued existence for being temporarily out of receptor contact, for example, for having disappeared from sight behind a screen. It is next to impossible to conceive of an intellectual genesis that would not presuppose either the innate or early acquired possession of this fundamental concept. Consequently, any demonstration that it is in fact a gradual acquisition rather than an initial given would qualify as a most important scientific discovery. Let us begin, then, by briefly summarizing Piaget's account of this acquisition.

Piaget's Analysis of the Growth of the Object Concept Piaget traces this growth within the 6-stage framework utilized in all of his descriptions of sensorimotor development. The age range associated with each stage is intended to be approximate only.

Stages 1 and 2 (0 to 4 months) When an object disappears from view, the infant will at most fixate for a time on the position where it was last seen. This is in itself very weak evidence for the lack of an object concept, of course, but it has significance in combination with what is seen in later stages.

Stage 3 (4 to 8 months) There are a number of relevant achievements during this stage, of which two are perhaps the most interesting. First, the child makes a primitive beginning at regaining contact with absent objects by extrapolating the accommodatory movements made to them during their presence, thus he may lean over to look for an object that fell to the floor rather than simply stare at the point where it disappeared from view, as would have been the case in Stages 1 and 2. Second, he acquires the ability to anticipate a whole object on the basis of seeing only a part of it. However, his behavior in this situation also testifies to the immaturity of his object concept: if a sufficient fraction of the object shows from behind the screen, he reaches for it, if this fraction is then made to decrease, the reaching hand abruptly drops. More generally, it is characteristic of this stage that the child makes no attempt to retrieve an object manually once it has disappeared from view (e.g., by being covered with a cloth), in spite of the fact that such activity would by this age be well within his physical capabilities.

Stage 4 (8 to 12 months) The child now regularly searches for objects which he has just seen move behind screens, at first only if already in the act of reaching for them at the moment of disappearance, and then without this restriction. However, this behavior pattern—surely a milestone in the genesis of the object concept—remains subject to an important limitation. Having had repeated success at retrieving an object hidden in one place, the child continues to search in that place when the object is then hidden elsewhere, despite the fact that its disappearance at the new location had clearly been attended to.

Stage 5 (12 to 18 months) The child over-

comes the previously mentioned limitation, now searching only where the object was last seen to disappear irrespective of what happened on previous trials. But this advance also contains the seeds of one further limitation: the child cannot yet infer invisible displacements, that is, further movements of the object after it has disappeared from view. Thus, if *E* carries a small object in his closed hand to a given hiding place and leaves it there, the Stage 5 child will search only where the object was last seen—in *E*'s hand.

Stage 6 (beginning at 18 months) At the end of the sensorimotor period the child becomes capable of representing whole sequences of invisible but inferable displacements, for example, if object-in-closed-hand is transported in succession to hiding places *A*, *B*, *C*, and *D*, the child will systematically search in all of them (and in the hand), as if he knew exactly what the possibilities were. At this point in development, Piaget is ready to credit him with a full-fledged concept of the independent and enduring object.

Replications and Extensions of Piaget's Work For reasons we need not mention here, all of Piaget's studies tend to constitute very powerful stimuli for replication behavior on the part of his reader. A lack of independent confirmation of his infancy work, however, ought to make a reader exceptionally uncomfortable, in view of the not overlarge sample of *Ss* (three), their relationship to the investigator, and the casual-looking tenor of his observations-interventions. One might have thought that there would have been a veritable stampede of would-be confirmers (or disconfirmers) for this segment of his work. However, for reasons that can only be guessed at (the difficulty of infant research and its relative unpopularity until recently), replication attempts are just now appearing on the scene, and some of the best are still in progress at this writing. The most important questions for follow-up work on object-concept development would seem to be these two: (1) Are the various behaviors *vis-à-vis* objects which Piaget observed in his three infants found in all normal infants? (2) Do these behaviors always emerge in the particular ontogenetic sequence he described?

There are three major replication studies, one completed (Goun-Décarie, 1965) and two still in progress (Uzgiris and Hunt, 1966a,

1966b, Escalona, 1966) The two projects in progress have as their eventual aim the construction of standardized developmental scales for testing sensorimotor intelligence Both are large-scale and extremely well-designed investigations, and they have already yielded what looks like very clear and trustworthy evidence concerning the genesis of the object concept In particular, their data strongly support three conclusions First, large samples of infants regularly show the very same behavioral reactions in this area that Piaget's three children did Second, standardized testing procedures for eliciting these reactions can be devised and the reactions elicited show very high interobserver and (short-term) test-retest reliability And, finally, the scalability of the test items turns out to be essentially perfect, that is, virtually no children ever show reactions characteristic of a later Piagetian stage while failing to have achieved those characteristic of an earlier one These studies also show promise of providing a wealth of additional detail about this evolution which Piaget, with his limited sample, could hardly have obtained For instance, Uzgris and Hunt (1966b) report what may be new intermediate or transitional reactions within Stages 5 and 6, and Escalona (1966) presents evidence suggesting a qualitative difference between Stage 6 performance and that of earlier stages

The purpose of Goun-Décarié's (1965) investigation was quite different she tried to show chronological parallels between the development of the object concept and the development of interpersonal-affective "object relations" (in the psychoanalytic sense of the term) Like Escalona and Uzgris and Hunt, Goun-Décarié's data on the former development unequivocally supported Piaget's conclusions, in terms of both content and content sequence (the scalability of her items also turned out to be perfect) The data on the genesis of object relations and their alleged parallelism with object-concept development were also suggestive, but much less unambiguous That some such parallelism must exist seems undeniable, since the significant people in the infant's life are, at minimum, also "objects" It is interesting in this connection that Schaffer and Emerson (1964) have recently shown that differentiated affective attachments to specific human objects occur at about the

same time the infant begins to search in earnest for absent objects (i.e., early in Stage 4) Finally, Woodward (1959) can claim credit for the earliest replication study in this area, if one is willing to accredit retardates as surrogate infants! She found that the order of difficulty of object-concept items for severely retarded older children closely corresponded to their ontogenetic order as described by Piaget

We shall close this section by describing two recent studies of a more innovative sort, methodologically innovative in the case of Charlesworth (1966) and substantively so in the case of Babska (1965) Charlesworth's investigation focused only on the acquisition of Stage 4 behavior, which he regards as the most important developmental step in the sequence His design was a combination longitudinal and cross-sectional one, 12 of his 58 infant Ss being retested monthly across the period of transition His procedure was as follows S is seated in a high chair and his attention is drawn to a small preferred object on the high chair tray E thereupon cups his hand over the object for 2 to 4 seconds and then removes his hand On some trials (Real Condition), the object is again visible after the hand is lifted, and on some (Trick Condition) it has miraculously disappeared, thanks to a small, foot-operated "trap door" in the tray The child's behavior throughout the procedure is filmed with a motion picture camera Charlesworth's Real and Trick Condition trials provide him with a rich and varied set of responses for developmental diagnosis The older infants could variously certify their Stage 4 status with behaviors such as these active search for the object while it is under E's hand, an immediate reaching response toward the object after the hand is lifted (Real Condition), surprise, puzzlement, change in affect, and active visual or manual search for the unaccountably missing object (Trick Condition) Charlesworth's data suggest that of the two, the Trick Condition is in general the more sensitive measure of the child's cognitive progress A global assessment of S's developmental status based upon such behaviors indicated that the transition to Stage 4 occurs at roughly 7 to 8 months, which accords fairly closely with Piaget's original findings Charlesworth is currently exploring the feasibility of measuring the in-

fant's autonomic responses in these conditions, as a more sensitive indicator of the infant's cognitive expectancies and his reaction to their violation (personal communication)

It might be supposed that the cognitive accomplishments of Stage 5, and especially of Stage 6, entail something more than just a tacit belief that the out-of-sight object continues to exist (the literal definition of the object concept). Also involved perhaps is a growing sensitivity to the cues that reliably indicate just where in space this existence is or could be manifested at the place where the object last was seen (Stage 5) or at the places its conveyor "touched down" during its itinerary (Stage 6). Babska (1965) has studied what may be still higher developmental forms of this sensitivity. Her test materials were sets of four grey, identical boxes with white cardboard covers, each cover exhibiting a different picture (e.g., a hen, a horse, a woman's face, and a cat). The child is presented with one of the boxes and is shown that it contains a toy. The box is then taken away for 15 seconds, after which it is shown again in company with the other three boxes of the set. *E* now asks *S* to find the toy and give it to her. The critical box (or the whole set of boxes) is changed from trial to trial, and the only reliable algorithm by which the child can always succeed in immediately finding the toy is to choose the one identical in appearance to that which was previously shown to contain the toy. Successful responding thus involves selective attention to the particular visual characteristics of the hiding place on each given trial, neither attending to spatial-position cues nor repeating the previous trial's correct response is an appropriate strategy here. Babska found that the transition to a consistent management of this type of problem occurs much later than sensorimotor Stage 6, it occurs at around 3 years of age. Her work appears to open up a number of research possibilities regarding the cognitive skills underlying the retrieval of absent objects under different circumstances—a research area that might be titled "Beyond the Object Concept."²

² An ingenious series of experiments by Bower (1967) has come to the author's attention since the completion of this chapter. Bower appears to have demonstrated that infants as young as 2 to

Quantity

A great many concepts are "quantitative" in the sense of being susceptible to precise enumeration or measurement—number, length, area, time, velocity, etc. However, this section deals only with the three that Piaget has usually subsumed under the name *quantité* substance (alternate designations: mass, matter, global quantity), weight, and volume. The development of these three concepts, and especially of their conservation, has been described in detail in one of Piaget's books (Piaget and Inhelder, 1941), there is elsewhere reported some additional evidence regarding conservation of substance (Piaget, 1952) and of volume (Piaget, Inhelder, and Szeminska, 1960).

Conservation of Substance, Weight, and Volume. We begin by briefly describing in turn the testing procedures used to assess non-conservation-conservation of each of these three concepts. In the case of substance, the procedure is as follows. Two quantities of a given material or substance *X* are initially established as equal, by virtue of having identical perceptual appearance or configuration. One of the two is then altered in some quantity-irrelevant way—for instance, changed in shape or divided into parts—and the child is asked if there is still "as much

3 months have what could be described as a perceptual version of the concept of object permanence. If an object disappears in an abrupt, discontinuous way (e.g., appears to "implode"), for example, the infant indeed acts as if it no longer existed for him, just as Piaget had suggested. However, if it disappears slowly and continuously (e.g., gradually moves behind a screen), he behaves for a time as though it were still present or would shortly reappear. Bower suggests that these primitive, perception-based discriminations regarding permanence and impermanence are later subordinated to conceptual rules—to the *concept* of object permanence. Unlike the 3-month-old, the 12-month-old has come to believe in the continued existence of certain objects (e.g., his mother) regardless of the psychophysical properties of their disappearance—even when his lower-order, perceptual operations have given him a verdict of out-of-existence rather than out-of-sight. If Bower's findings prove valid (his studies certainly should be replicated), they will substantially augment and elaborate our understanding of this highly important sector of human epistemological growth.

"X" (or some equivalent expression) in the one as in the other. Several different materials have been used. The child may be presented with two identical balls of clay or plasticine, one of which is then elongated, flattened, cut into pieces, etc., prior to the conservation question. Or he may be given two identical glasses containing equal quantities of liquid, one of which is then poured into a narrower or wider glass, or into several little glasses. Or, as we have already seen, the contents of the glasses may be marbles or beads, the test thereby amounting to a variation on the standard conservation of number problem (conservation of "discontinuous" as opposed—in the case of clay and water—to "continuous" quantity).

Whichever procedure is used, the physical transformation which *E* has wrought in one of the quantities presents *S* with the temptation to index the relative amounts perceptually—by noting the differential heights of the liquid column in the standard and comparison glasses, the greater length of the elongated clay ball, etc.—rather than conceptually—by invoking the knowledge that nothing has been added or taken away during the transformation, etc. As in the number conservation test, the younger, nonconserving *S* succumbs to the temptation, assesses the quantities in terms of some one, striking perceptual feature, and wrongly concludes that there is "more X" here than there, for example "more water" in the narrower glass because of its higher liquid column.

As in the area of number, we still have much to learn about the cognitive structure and content of children who do and do not conserve global quantity or substance. It can at least be said that "amount" for the non-conserver is not yet a multidimensional affair, unreliably estimable by consideration of only a single dimension, everything points to the fact that the young child is quite content to estimate quantity (and, as subsequent sections will show, many other physical variables) by means of a single cue such as height. In the case of substance conservation particularly, however, an exact intellectual characterization of the conserver is equally difficult. For the present, it will suffice to point out two components his quantity concept need *not* have and, indeed, regularly does not have when the conservation we are

discussing is first attained. (1) There is no recognition that the weight and the volume of the transformed object—the very attributes by which its quantity or "amount" could be precisely measured—also remain invariant under the transformation. (2) The concept of "amount" that the child first attains, and to which he correctly ascribes quantitative invariance in the face of all manner of irrelevant physical changes, appears to be a global, nonmeasurable affair, not yet anchored to the more precise concepts of weight and volume.

In the case of weight, the materials regularly used are the clay or plasticine balls. After initially establishing that the two balls keep the arms of a scale balance horizontal when placed on opposite pans (and/or are judged equally heavy when held in the child's two hands), one of them is transformed (change of shape or division into pieces) and the child is asked if they still weigh the same, or would continue to balance on the scale. Two procedures have been used to assess conservation of volume. In the one devised earlier (Piaget and Inhelder, 1941, Chap. 3), the child is shown that a clay ball placed in a vessel of water causes the water level to rise to a certain point (which *E* carefully marks). After the child agrees that a second, identical ball would make the water rise to the same height, this ball is transformed in any one of the usual ways and the child is asked if it will now take up the same amount of space in the water, if it will make the water rise to the same point. In the later procedure (Piaget, Inhelder, and Szeminska, 1960, Chap. 14), 36 small metal cubes are arranged and rearranged to make different "houses" and the child is asked if all these houses have the same amount of "room" in them. The same materials have also been used in the older procedure for comparative purposes: the little cubes are put in a vessel of water and the child is asked to predict the height of the water level when the same cubes are rearranged in different configurations.

According to Piaget, the child attains conservation of these three concepts in an invariant developmental sequence: first substance (early middle childhood), then weight (late middle childhood), and finally volume (early adolescence). However, a number of studies by Piaget (Piaget, Inhelder, and Szeminska, 1960) and other (Elkind, 1961b, 1961f,

1962c, Lovell and Ogilvie, 1961a, Lunzer, 1960b, Uzgris, 1964) have shown that the mean age of volume-conservation attainment is very much a function of the method used to test for it. For example, there is the finding by Piaget, Inhelder, and Szeminska (1960, Chap. 14), subsequently confirmed by Lovell and Ogilvie (1961a), that the recognition that the different "houses" constructed from a common set of cubes all have the same amount of room inside is normally acquired several years earlier (i.e., roughly concurrent with weight conservation) than the recognition that they will all cause the surrounding water to rise to the same level. Piaget, Inhelder, and Szeminska refer to the former as the conservation of "interior volume" and to the latter as that of "occupied volume."

On the other hand, studies by Elkind (1961b, 1961f, 1962c) and Uzgris (1964) have shown that there are some perfectly reasonable-looking versions of the volume-conservation task which most early adolescents fail and which only an unimpressive majority of college students pass (Elkind, 1962c). The present writer has so far been unable to find a wholly satisfactory explanation for the extremely wide variation in difficulty level across these various tasks. He suspects, however, that the easiest ones may really be tapping a slightly refined form of substance conservation and that it is the more difficult ones which, despite their undoubted psychometric impurities, come closer to assessing what the individual really understands about volume per se and about the conditions under which it remains invariant.

Assuming for the moment that conservation of substance, weight, and volume are achieved in that ontogenetic order, how might this particular order be explained? The following is a highly oversimplified account of Piaget's attempt at explanation (Piaget and Inhelder, 1941, Piaget, Inhelder, and Szeminska, 1960, see also Flavell, 1963a, pp. 300-303). The ability to conserve substance or global quantity emerges from two schemas or skills developed early in the concrete-operational period. On the one hand, the child becomes capable of multiplying relations, for example, imagining that the elongated ball's added length may be compensated by its decreased thickness. On the other hand, he attains a kind of part-whole or "atomistic" conception

of substances: an intuition that a given amount of substance is composed of a fixed number of small parts or unit-amounts, which merely change their position in space under the standard transformations (in effect, a kind of number-conservation schema applied to continuous rather than discontinuous material). However, for various reasons having to do with his initial, egocentrically tainted conception of weight, the child is not at first ready to assume that the weight of these unit-amounts remains the same regardless of their locus within the whole, and hence there remain further obstacles to overcome before conservation can be generalized to this property. And, finally, there are still more advanced schemas and skills which must get into the repertoire before conservation of volume becomes a possibility: a clear differentiation between weight and volume and some grasp of their relationship within an atomistic conception (objects which are heavy for their volume are composed of dense, closely compacted units), an understanding of certain properties of lines and planes, which makes possible a metric, three-dimensional conception of volume.

Subsequent Research on the Quantity Conservations. As was true in the area of number, Piaget's work on substance, weight, and volume conservation has received a considerable amount of research attention by other investigators. Some of the relevant studies on volume conservation have already been cited. Additional evidence will now be presented by means of the stratagem used in the section on class concepts: describe a well-executed, prototypical study, and ring the findings of other investigators around its results. The best study for this purpose (and perhaps the best study in the area on most counts) is that by Uzgris (1964). Tests of conservation of substance, weight, and (occupied) volume were individually administered to 120 first- through sixth-grade children. Four different types of material were used in testing for each of the three conservation concepts: plasticine balls, metal nuts, wire coils, and straight pieces of insulated wire. There were two principal findings.

Conservation of substance, weight, and volume are almost invariably achieved in that order for each of the four types of material. Out of 120 Ss, only 8 showed a deviation

from this sequence on some one of the four materials. There are at least eight other studies that give evidence on this alleged substance-weight-volume sequence (in addition, of course, to Piaget's original positive findings, see Piaget and Inhelder, 1941, p. 12). Of the eight, the data of six either explicitly demonstrate (Chittenden, 1964, Kooistra, 1965, Sigel and Mermelstein, 1966, Smedslund, 1961b) or imply (Elkind, 1961b, King, 1963) a near-exceptionless sequence of acquisition for these concepts, whereas two (Beard, 1963b, Hyde, 1959) apparently find numerous deviations from the modal order. The combined evidence for the developmental gap (or, in Piaget's lexicon, developmental *décalage*) between weight and volume appears to this writer to be somewhat more compelling than that for the substance-weight *décalage* (e.g., Kooistra, 1965), and it may turn out that a small minority of children somehow achieve conservation of weight before or in rough synchrony with conservation of substance (Lovell and Ogilvie, 1960, found that a few children actually appeal to weight invariance in justifying their substance conservation responses). On the other hand, the data from some of the more carefully designed studies in this area (e.g., Chittenden, 1964, Uzgris, 1964) are very convincing, and the research consensus may someday be that there is in fact a universal sequential invariance here, an invariance at the level of cognitive-structural genotype as contrasted with verbal-behavioral phenotype.

Uzgris' second major finding was that there is a fair amount of individual inconsistency in level of conceptual response across task materials, especially at certain ages. Uzgris offers the highly reasonable suggestion that it is the child in a transitional phase with respect to some conservation concept who is most subject to variation in performance concerning that concept as a function of specific features of the task situation, once the concept is well-consolidated, this situational variability would be expected to diminish. As will be shown later in the chapter, this interaction, possibly age-dependent, between performance level and task features is scarcely limited to the area of quantity concepts. Within this area, however, Beard (1963b), Lovell and Ogilvie (1960, 1961b), and Pratoomraj and Johnson (1966) have like-

wise noted that conservation judgments are partly dependent on the specifics of the task. Lovell and Ogilvie (1961b), for example, have shown that weight conservation judgments may be importantly influenced by the kind of transformation performed upon the materials: many children who recognized that the weight of an object is not altered when its shape changes still believed that making it harder or softer (water cooled until it turned to ice, hard butter allowed to soften, etc.) would change the weight.

It must be obvious that the research questions posed by Uzgris and these other investigators are not the only ones, nor the only important ones, that might be asked about the ontogenesis of quantity concepts. There is, for instance, the vital problem of identifying the cognitive antecedents or "ingredients" of these various conservation concepts and, once identified, of determining their necessary- versus sufficient-condition status as "causes" of these concepts. However, this and other important problems are also better deferred to later chapter sections, so that they may be given a more general treatment. Suffice it to say here that Piaget's account of the cognitive acquisitions underlying these particular conservations has already come under fire (e.g., Bruner, Olver, and Greenfield, 1966, Lunzer, 1960b), and that there are a number of vexing methodological and theoretical problems involved in trying to decide what constitutes adequate research evidence on this sort of developmental question. One final investigation is worth citing if only because it can scarcely be well known as yet. In an unpublished doctoral study (1965), Anderson has found an increase from grades 3 through 6 in children's disposition to utilize atomistic conceptual models to explain the attributes and behavior of various natural phenomena such as water.

Space

This section reviews studies of the development of such spatial concepts as the conservation and measurement of length, distance, and area. As with previous topics, Piagetian or Piaget-inspired studies come close to exhausting the significant research literature in this area.

Piaget's Theory and Research on the Development of Spatial Concepts. Piaget makes

a rather sharp distinction between the perception and representation of space (Piaget and Inhelder, 1956) The theory and research under discussion concerns representation rather than perception the evolution of the child's intellectual representations and operations with regard to the spatial world—developmental changes in "how the child thinks about space" (*ibid.*, p. xi) His theory makes several claims about this evolution, of which the following two are held to be particularly important First, an adult's cognitive representation of space derives from an ontogenetic history of actions performed upon objects, rather than from a history of direct perceptual "readings" of their properties, the way we eventually come to apprehend our spatial surroundings is thus primarily a function of past doings rather than past seeings Second, not all the various spatial-geometric properties are acquired at the same time In particular, topological properties (proximity, order, etc.) are said to be attained first, and then to provide a developmental foundation for later-acquired projective (perspectives, etc.) and Euclidean (rectilinear coordinates, etc.) properties

Special theoretical and research attention has been given to the mastery of Euclidean concepts (Piaget and Inhelder, 1956, Part 3, Piaget, Inhelder, and Szeminska, 1960) The following passage describes what Piaget believes to be one of the major intellectual components of this mastery

What the child needs eventually to establish—and does not at first possess—is a picture of space as a kind of all-enveloping container made up of a network of sites or subspaces Within the container are objects, the things contained, which move from site to site, now occupying or filling a given site, now leaving it unoccupied and empty Measurements of various kinds can be made within the container without regard for whether the sites along which the measurements occur are occupied or not For example, the straight-line distance from me to you is the same whether or not the space between us is occupied by objects, whether or not the intervening spatial sites are filled or empty Similarly, if I slide a block of wood along the table, the metric value of the space it occupied before the movement (its length, its surface area, its

volume) is precisely equivalent to that of the space it presently occupies, even though the former is now empty and the latter is now filled In short, the child has finally to conceive of space as a medium which is homogeneous throughout from the point of view of measurement, in spite of its heterogeneity as regards filled versus empty subspaces or sites (Flavell, 1963a, p. 335)

The two Piaget volumes cited above report some three dozen developmental studies, and it is obviously impossible to summarize them all here Several deal with the acquisition of various topological concepts (Piaget and Inhelder, 1956, Part 1) In one, Piaget and Inhelder claim to show that the child can distinguish, in both tactual discrimination and graphic reproduction task settings, topological features (e.g., a closed versus an open ring) earlier than he can discriminate Euclidean features (e.g., a square versus a triangle) Several other studies point up the child's initial difficulties with the topological property of order or sequence, for example, his inability to invert an order and to transform a circular order into a simple linear one These experiments on spatial order have a better-known ancestor, reported in an earlier book (Piaget, 1946b) *E* slides three different-colored wooden balls into, say, the left-hand opening of a tunnel in a particular order (*A*, then *B*, then *C*), and then asks *S* a series of questions In what order will the three balls exit at the right hand end of the tunnel (*ABC*)? In what order would they reemerge on the left side (*CBA*)? What will be the order of appearance on the right side when the whole tunnel is rotated 180° (*CBA*), or 360° (*ABC*), etc? Pre-operational children tend to have problems with all but the first question, and occasionally even predict that the middle ball (*B*) will emerge first under one or another of the experimental conditions Above all, they seem to lack any sense of a rule system governing the occurrence of direct versus inverse orders under the various rotations and directions of exit

Another group of studies dealt with the acquisition of projective-geometric properties, especially with the child's growing awareness that a given object or array of objects has a different visual appearance when looked at from different viewpoints, and that its appear-

ance from any given perspective may be "computed" from the cues presented (Piaget and Inhelder, 1956, Part 2) Consideration of this research will be deferred to the section titled Psychological Concepts, however, since the behavior in question can equally be construed as an instance of social-psychological (i.e., role-taking) cognitive activity

The list of investigations centering on Euclidean-geometric acquisitions is much longer. The concept of an iterable (i.e., capable of repeated application) measurement unit is seen as one of the crucial mediators of operational progress in this area (Piaget, Inhelder, and Szeminska, 1960, Chap 15). Reminiscent of the atomistic view of substance described in the previous section, it refers to the view that a given length (distance, area, volume) is potentially divisible into equal, unit part-lengths of arbitrary size, the total length thus being precisely measurable by repeatedly (iteratively) displacing one of these units along its entire extent. The following experiment nicely illustrates the developmental growth of this concept (*ibid*, Chap 2). The child is shown a block tower and asked to build another one of the same height. Conditions are so arranged that measurement is necessary for exact replication (e.g., the child cannot see the model while actually constructing the duplicate and the blocks available for the duplicate are of a different size than those used in the model), and various-sized sticks and paper strips are put at the child's disposal. The behavior of Piaget's Ss on this task yielded a rich sequence of developmental stages and substages, among which the following are particularly revealing. The basic transitivity property inherent in all metric comparisons eludes the youngest children, that is, that the establishment of A (the model tower) $= B$ (a stick of the same length), and $B = C$ (the duplicate tower), permits the certain inference $A = C$. This failure to utilize spontaneously a common measure recalls the developmental evidence on transitivity of symmetrical relations presented in an earlier section of this chapter (Relations). Also, only toward the middle of the concrete-operational years do children have a conception of length that allows them to utilize a stick or strip *shorter* than the model as an iterable unit measure—"the

tower I must build is exactly three-sticks-plus-this-much-leftover high"

Possession or nonpossession of this unit-parts schema almost certainly influences the child's response to some of the conservation of length problems Piaget has invented (*ibid*, Chap 5). He has shown, for example, that young children fail to maintain an initial judgment of length equivalence when one of two originally identical strips of paper is cut into pieces and the pieces are set end to end to form a jagged line, the reason is that they attend only to the endpoints of the line, rather than to its constituent part-lengths (the sequence of pieces).

The schema of empty and filled subspaces described in the preceding quotation is also thought to mediate conservation of length (*ibid*, Chap 4) and, especially, conservation of distance (*ibid*, Chap 3). As to conservation of length, Piaget has shown that two identical sticks of wood initially judged to be of equal length when placed side by side so that their ends coincide are, incredibly, no longer so judged by the young child when E slides one ahead of the other. The child appears to focus his attention solely on the leading edge of the stick that was moved, failing to note that the space which this front edge fills is equal to the space which its hind edge vacates. Conservation of distance is assessed by placing two objects at a certain distance from each other, having the child globally code this distance (e.g., "they are far apart"), and then asking him if they are "still just as far apart" after a cardboard screen is interposed between them. There is a stage in development when the child thinks the distance is now less than it was because he does not "count," as part of the total distance, the space occupied by the screen. If a small window is put in the screen, for instance, the distance between the objects is actually thought to increase when the window is open and diminish when it is closed!

Other studies deal with the apprehension of two-dimensional rather than one-dimensional Euclidean space. In one of these investigations, an assessment was made of the extent to which the young child "sees" objects as embedded in a two-dimensional spatial framework—the Euclidean "grid" of horizontal and vertical coordinates (Piaget and Inhelder, 1956, Chap 13). In the case of hori-

zontal coordinates, for example, the child is shown a glass jar with colored water in it and asked to predict (e.g., gesturally) the spatial orientation of the water level when the jar is tilted in various ways. At one stage, the child systematically predicts that the water line will remain perpendicular to the sides of the jar, regardless of how the jar is tilted—he appears to represent the water level with reference to a local and immediate rather than generalized spatial framework. A recent study by Smedslund (1963b) clearly shows that laboratory experience in actually observing the invariance of water level under tilt has little effect on the predictions of children who showed no signs of recognizing this invariance before training, like other cognitive immaturities Piaget has described, this one appears to be less corrigible than common sense would suggest. A related study by Piaget, Inhelder, and Szeminska (1960, Chap. 7) showed that younger children are also insensitive to the need for taking into account both vertical and horizontal axes when trying to measure an object's position in two-dimensional space (given a piece of paper with a dot on it, reproduce the exact position of the dot on a second piece of paper without recourse to superposition).
